Thermoelectrics have a wide variety of applications, but their efficiency, typically stated in terms of the figure of merit  $ZT$ , must be improved before they become economical for non-niche applications. According to theory [1, 2],  $ZT$  can be improved relative to the bulk by constructing devices that feature nanometer-scale confinement in one or more dimensions. Here we describe transmission electron microscopy (TEM) observations of cooling in heterojunctions constructed from 2D flakes of exfoliated bismuth telluride and bismuth-antimony telluride.

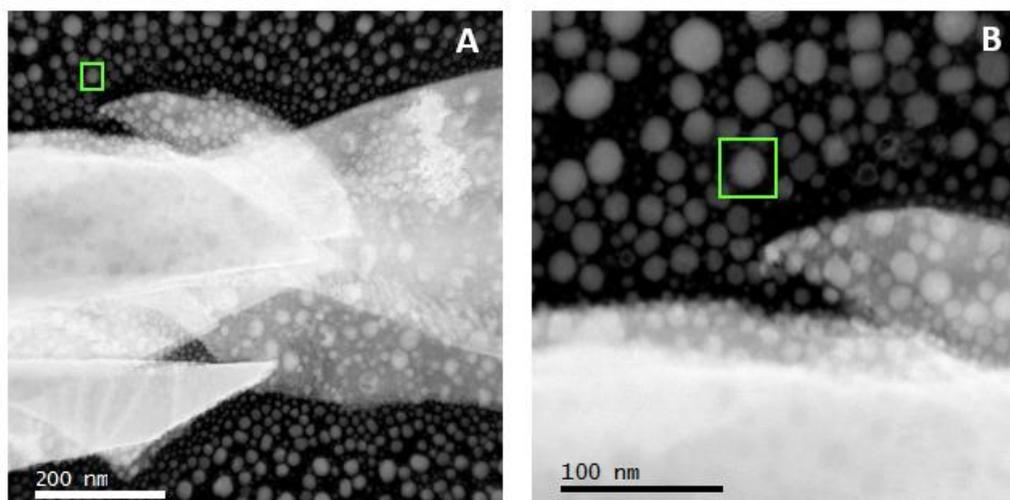

A ‘quintuple’ of bismuth telluride consists of five atomic layers and is one nanometer thick [2]. Such thin layers could, in principle, improve  $ZT$  by a factor of 13 [1]. Observations have shown  $ZT$  enhancement of 30-40% [2]. In this preliminary work, we report measurements on thermoelectric junctions between many-quintuple layer exfoliated bismuth telluride and bismuth-antimony telluride (see Figure 1). Using scanning TEM electron beam induced current (STEM EBIC) [3], we confirmed the existence of a p-n junction at the interface between two flakes that were overlapped using wet-transfer methods.

To investigate the cooling properties of the junctions, we applied plasmon energy expansion thermometry (PEET) [4]. Because the bulk plasmons in bismuth telluride and bismuth-antimony telluride have broad widths, we evaporated indium nanoparticles onto the supporting silicon nitride membrane to serve as local nanothermometers. Applying PEET to one nanoparticle near the heterojunction, we measured this particle’s temperature as a function of the reverse-bias junction current (see Figure 2).

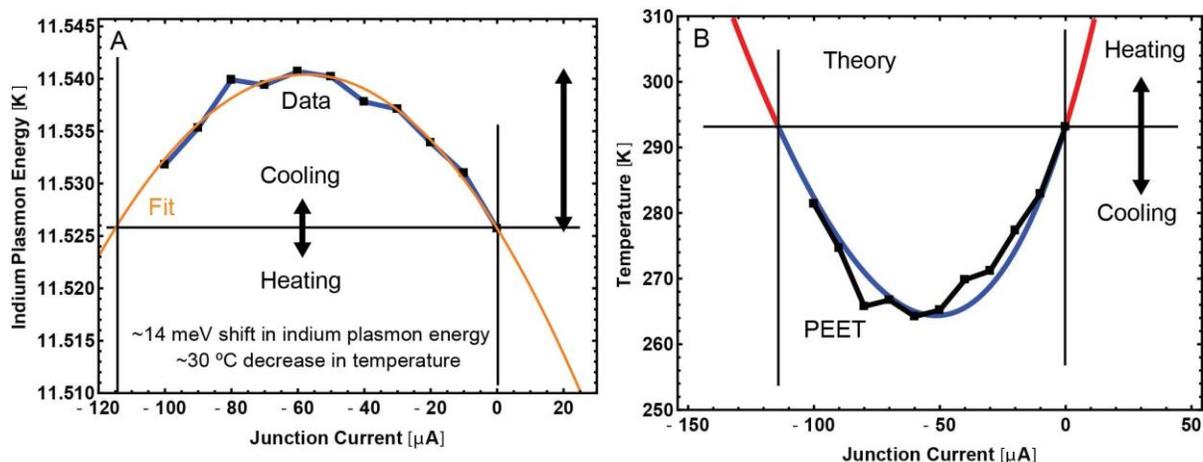

The temperature decreased with increasing current magnitude until the junction current ( $I$ ) reached  $-60 \mu\text{A}$ . At this point the Joule heating (proportional to  $I^2$ ) began to dominate the Peltier cooling (proportional to  $I$ ). Interpreting the 14 meV shift in the indium plasmon energy in terms of indium’s linear thermal expansion coefficient of  $3 \times 10^{-5} \text{ K}^{-1}$ , we find the device to have cooled by approximately 30 K, which is below the freezing point of water. This performance, good for a single stage cooling device [5], is especially impressive considering the thermal short through the supporting 15 nm-thick silicon nitride membrane. COMSOL modeling of this junction, subject to admittedly large uncertainties, produces smaller temperature shifts than those observed. Further scaling and more complete, quantitative measurements using STEM EBIC and PEET will allow a more definitive determination of the possibilities for significantly improving  $ZT$  via nanostructuring such layered materials as bismuth telluride and bismuth antimony telluride.
