Submitted 7 October 2008: Accepted 2 March 2010: First published online 22 April 2010

Abstract

Objective: To investigate the efficacy of biscuits fortified with different doses of vitamin A on improving vitamin A deficiency (VAD), anaemia and physical growth of pre-school children.

Design: A randomised double-masked population-based field interventional trial with a positive control group.

Setting: Banan district of Chongqing, China.

Subjects: A total of 580 pre-school children aged 3–6 years were randomly recruited into four groups. Children in groups I and II were given biscuits fortified with vitamin A at 30% of the recommended daily intake (RDA) and 100% of the RDA once a day for 9 and 3 months, respectively. Children in group III received biscuits containing 20 000 IU of vitamin A once a week for 3 months. Initially, the children in group IV received a 200 000 IU vitamin A capsule just once. At the beginning and end of the study, blood samples were collected to measure Hb, serum retinol, retinol-binding protein and prealbumin, and weight and height were measured.

Results: All the fortification types significantly decreased the prevalence of VAD and anaemia in each group ($P < 0.05$). The effect of 9-month intervention on group I was the most efficient ($P < 0.0045$). After intervention, the Z-scores of height-for-age, weight-for-age and weight-for-height in all groups increased markedly compared with baseline ($P < 0.05$), but no significant difference was observed among the groups.

Conclusions: Data indicated that consuming vitamin A-fortified biscuits with daily 100% RDA for 3 months has the same effect on the improvement of VAD, anaemia and physical growth as did the weekly 20 000 IU and single 200 000 IU administration in pre-school children.

Pre-school children
Fortification

Anaemia and vitamin A deficiency (VAD) are widespread public health problems associated with increased risk of morbidity and mortality, especially in young children⁽¹⁾. The Chinese Food and Nutrition Surveillance System documented that the prevalence of anaemia in pre-school children remained at 16–20% in the 15 years from 1990 to 2005⁽²⁾. Except for iron, other nutritional deficiencies, such as that of vitamin A, may also adversely affect haematopoiesis and lead to anaemia⁽³⁾. A national nutrition and health survey in 2002⁽⁴⁾ revealed an incidence of 45.1% for marginal VAD and 9.3% for VAD in Chinese children aged 3–12 years. At present, VAD is more serious among pre-school children in China⁽⁴⁾ because their diets mainly consist of rice with low iron availability and without preformed vitamin A or provitamin A.

High-dose vitamin A supplements are recommended as part of the treatment⁽⁵⁾. However, clinical trials that examined the effect of a high dosage of vitamin A on children with diarrhoea or respiratory infections showed that it had either no efficacy⁽⁶⁾ or only minimum efficacy⁽⁷⁾, or even adverse effects⁽⁸⁾. Small doses of vitamin A given regularly might be a better strategy to improve VAD status and anaemia and reduce morbidity but they have been rarely tested.

Recently, several randomised controlled trials^(9,10) have shown micronutrient-fortified biscuits to be a feasible, practical and effective way to improve the micronutrient status of primary-school children from the poor rural community. However, there is as yet no research to evaluate the effect of biscuits fortified with different doses of vitamin A on serum vitamin A nutritional indices, Hb and the physical growth levels of pre-school children.

† Both authors contributed equally to this work.

In the present study, we conducted a randomised controlled study to investigate the efficacy of biscuits fortified with different doses of vitamin A on improving serum vitamin A and Hb status, physical growth of pre-school children aged 3–6 years in a suburb in Chongqing, China. We hypothesised that providing lower doses of vitamin A through daily provision of fortified biscuits was as efficacious in reducing the prevalence of VAD and anaemia as a higher dose of vitamin A administration.

Subjects and methods

Subjects and ethical approval

This intervention programme was performed in Banan district of Chongqing from March to December 2002. Approximately 1000 pre-school children aged 3–6 years were randomly recruited from about thirty kindergartens in the region. The eligibility criteria for participation were as follows: (i) apparently good health; (ii) Hb concentration ≥ 60 g/l; (iii) C-reactive protein (CRP) < 10 mg/l; (iv) parental or guardian's approval for participating in all aspects of the study; and (v) parental/guardian's agreement to avoid additional use of vitamin and mineral supplements during the investigation. Children with evidence of recent acute or chronic illnesses and/or Hb < 60 g/l were not included in the study and were referred to a local medical centre for treatment.

The primary outcome objective for the present study was the change between pre- and post-intervention in serum retinol concentration. A sample size of about 135 pre-school children per group was sufficient to allow the detection of a difference of $0.04 \mu\text{mol/l}$ in serum retinol concentration, 5.3% prevalence of VAD and 13.0% prevalence of anaemia among the four interventions over 3 months with 90.0% power and $\alpha = 0.05$ for two-sided one-way ANOVA. Considering the loss of children over the duration of the study, we initially managed to recruit more than 200 children per group. However, the primary outcome measures including analyses of micronutrient status of blood and anthropometric indices before and after intervention were obtained from 580 pre-school children, due to the loss to follow-up in the present trial.

Informed written consent was obtained from the parents/guardians. The enrolment and research plan were reviewed and approved by the institutional ethics committee of the Children's Hospital of Chongqing Medical University in Chongqing, China.

Information on the socio-economic and demographic parameters of the children and their families was collected.

Intervention

The present study used fortified biscuits directly for oral application with dairy products, such as bean milk or soup. The biscuits of all four packages were similar in macronutrient composition (71.3 g carbohydrate, 8.0 g

protein, 16.0 g fat, 2.2 g fibre and 1856.8 kJ per 100 g biscuit) and were indistinguishable in taste, colour and packaging, except for the coded numerical labelling. Package I biscuits contained 30% of the recommended daily intake (RDA; set by the Chinese Nutrition Society) for vitamin A (500 IU as dry vitamin A acetate) per piece, and package II had 100% of the RDA for vitamin A (1666 IU as dry vitamin A acetate) per biscuit piece. Package III contained biscuits with supplements of 20 000 IU of vitamin A (as dry vitamin A acetate) per piece, while package IV had no vitamin A and was used as placebo biscuit. All of the biscuits were provided by Shanghai Danone Biscuits Foods Co., Ltd (Shanghai, China) (2002–2003) and the concentration of fortification was determined by Shanghai Roche Pharmaceuticals Ltd (Shanghai, China).

The study was designed as a double-blinded, randomised and positive-controlled trial. With the help of child health-care workers, the children who met the eligibility criteria in all of the nurseries were randomly assigned to one of the four groups within the sex and age strata to help ensure sex and age balance of treatment allocation. The RAND function of Excel (Microsoft, Redmond, WA, USA) was used to generate computer randomly permuted codes. Pre-school children in groups I and II were given fortified biscuits packages I and II once a day for 9 and 3 months, respectively. Children in group III were provided with biscuit package III once a week for the interval time for 3 months. Lastly, children in group IV received a 200 000 IU vitamin A capsule (as retinyl ester) just once initially and then biscuit package IV for the rest of the time for 3 months.

Fortified biscuits were given to each child at afternoon snack time, 5 d/week during the study period for all groups. Children in group III were given biscuit package III only on every Monday afternoon. No intervention took place during school holidays or public holidays, and the biscuits were provided for a total of 59 school days (the equivalent of 12 weeks). The investigators, food preparers, teachers, outcome assessors and children were not made aware of the intervention assignment for the duration of the study until after the completion of data analysis.

Blood sample collection and biochemical measurement or assessment

At the beginning and at the end of the 3-month period (children in group I who received two measurements or assessments at the end of the 3-month period were designated as group I-3, and those who received measurements at the end of the 9-month period were designated as group I-9), two or three (for children in group I) blood samples (about 1.5 ml) were collected by venepuncture of an antecubital vein from each subject before breakfast. A volume of 0.5 ml was drawn into a container with heparin to measure Hb by the hemiglobincyanide

method⁽¹¹⁾ (MAKER, China). The concentrations of serum retinol-binding protein (RBP) and prealbumin (PA) were measured by ELISA⁽¹²⁾ with commercial ELISA kits (Sunbiote, China). CRP was measured by particle-enhanced immunoturbidimetry⁽¹³⁾ (catalogue no. 67274; Orion Corporation Orion Diagnostica, Finland). Serum retinol concentration was determined by using HPLC following the method of Miller and Yang with slight modification⁽¹⁴⁾. All of the biochemical indices were measured by experienced examiners in the Pediatric Laboratory of Chongqing Medical University.

Anthropometric measurements

Anthropometric examinations in any one group were conducted by the same trained anthropometrist (a total of four) from the Chongqing Children's Hospital at the baseline and follow-up (3- or 9-month) time points using standardised techniques to eliminate intra-examiner error. By using reference data from the US National Center for Health Statistics/WHO (2005), Z-scores were calculated for height-for-age (HAZ), weight-for-height (WHZ) and weight-for-age (WAZ). A cut-off of less than minus two standard deviations (-2 sd) was used to define stunting (HAZ < -2) and wasting (WHZ < -2), while a cut-off of more than plus two standard deviations ($+2$ sd) was used to define obesity (WHZ $> +2$)⁽¹⁵⁾. All indices were computed using the ANTHRO software (Anthro 2005 PC) recommended by WHO (<http://www.who.int/childgrowth/software/en/>).

Simultaneously, assessment of symptoms and signs of VAD (xerophthalmia, Bitot's spots and/or night blindness) of pre-school children was performed by paediatric ophthalmologists.

Definition of outcomes

The prevalence of deficiency for some biochemical indices was expressed as the percentage of pre-school children below the cut-off value. Prevalence of anaemia was determined according to the WHO criteria, i.e. Hb < 110 g/l for 5-month to 6-year-olds and Hb < 115 g/l for 6–11-year-olds⁽¹⁶⁾. According to the WHO criteria⁽¹⁷⁾, a serum retinol concentration of < 0.7 $\mu\text{mol/l}$ was classified as VAD and values between 0.70 and 1.05 $\mu\text{mol/l}$ were defined as marginal vitamin A deficiency (MVAD). CRP levels of > 10 mg/l indicated infection or inflammation as recommended by the manufacturer (Roche Diagnostics).

Statistical analysis

Using the Kolmogorov–Smirnov goodness-of-fit test, the distribution of each set of data was tested for normality prior to analysis. Data were presented as the mean and sd for normally distributed variables or median (25th, 75th) for skewed distribution variables and, when necessary, data were normalised using natural-log transformations. Tests of significance were two-tailed and $P < 0.05$ was considered statistically significant. Paired Student's *t* tests were used to compare paired data with normal distribution

and homogeneous variance in the before–after intervention pairs of each group, while paired Wilcoxon sign-rank test was used for skewed distribution data. The χ^2 test was used for categorical variables, with a Bonferroni correction for multiple comparisons among multiple groups. In order to compare the different effects among the four interventions, we performed multiple comparisons of the changes of parameters over the 3-month intervention ($P < 0.05$ set for statistical significance) with Student–Newman–Keuls (SNK) test (normal and homogeneous data) or SNK rank test (skewed data). For SNK test or SNK rank test, the SNK grouping letters were provided. Data were analysed using the SAS for Windows statistical software package version 8.1 (SAS Institute Inc., Cary, NC, USA).

Results

Seven hundred and fifty-three children met the inclusion criteria (177 for group I, 173 for group II, 209 for group III and 194 for group IV). About 23.0% (173/753) dropped out during the course of the study. The dropout number was forty-two (four for blood drawing failure and thirty-eight for moved during trial) for group I, thirty-two (three for blood drawing failure and twenty-nine for moved during trial) for group II, forty-four (two for blood drawing failure and forty-two for moved during trial) for group III and 55 (six for blood drawing failure and forty-nine for moved during trial) for group IV, respectively. Thus, primary outcome measures including analyses of micronutrient status of blood and anthropometric indices at the end of intervention were obtained from 580 pre-school children (135, 141, 165 and 139 from groups I, II, III and IV, respectively; Fig. 1). Retrospective data documented daily by caregivers indicated about 95% compliance, suggesting that at least 95% of the pre-school children took the biscuits during the study period.

Baseline characteristics

The demographic characteristics of the children studied are given in Table 1. There was no significant difference in clinical characteristics among the treatment group children who completed the study. Similarly, no marked difference in the parameters mentioned above was found between the children who completed the study and those who dropped out ($P > 0.05$).

Effects of intervention on the prevalence of vitamin A deficiency and anaemia

At baseline, about 7.6% (57/753) of the children had VAD and 34.8% (262/753) of them had MVAD. The prevalence of anaemia was 26.6% (200/753) before intervention and 2.0% (15/753) of the children had both VAD and anaemia. No significant difference was observed for the prevalence of VAD ($\chi^2 = 0.97$, $P = 0.81$) and anaemia ($\chi^2 = 4.89$, $P = 0.18$) at baseline among the treatment groups. After the 3-month intervention, the four ratios

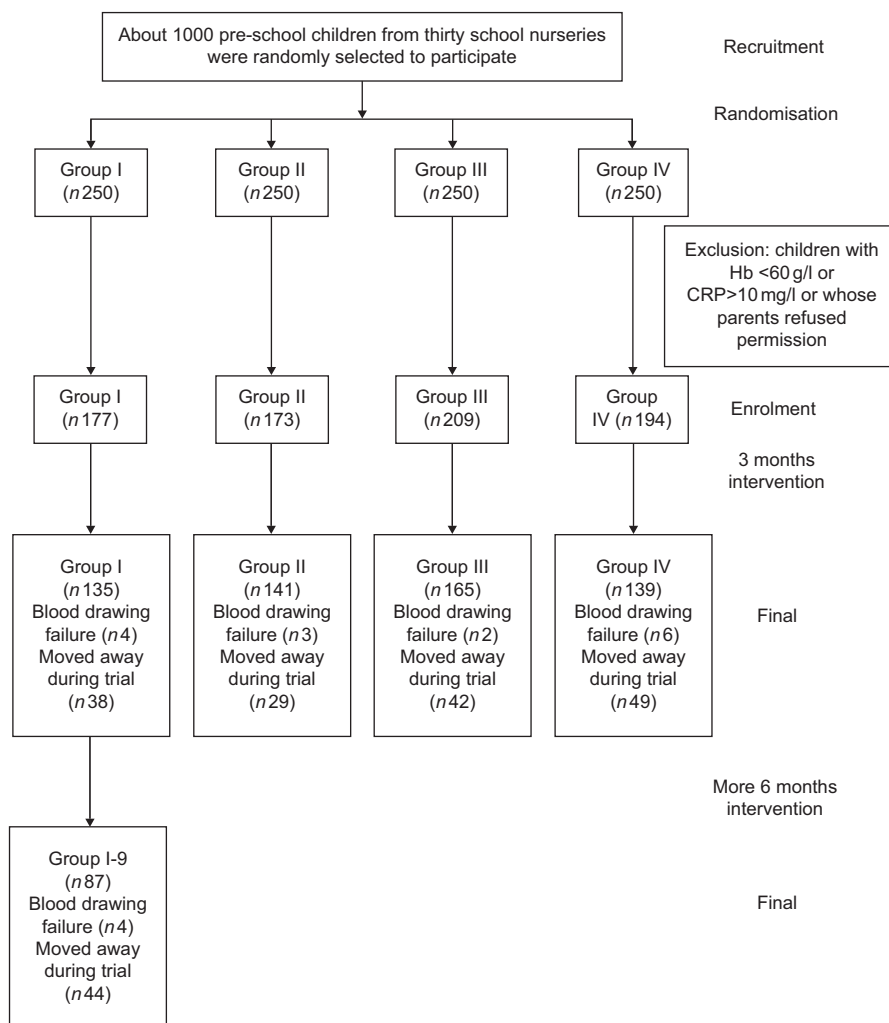

Fig. 1 Trial profile showing the number of participants randomly assigned, completing the trial, and analysis of the primary outcome (CRP, C-reactive protein)

mentioned above decreased to 1.6% (9/580), 30.5% (177/580), 10.3% (60/580) and 0.2% (1/580), respectively. Meanwhile, the prevalence of VAD and anaemia in all groups, including the children with the 9-month supplementation, decreased significantly ($P < 0.05$; Table 2). No significant difference in the prevalence of VAD between groups after the intervention was found with the multiple comparative Fisher's exact test (Table probability = 0.06, $P = 0.36$). But the prevalence of anaemia after intervention in group I-9 was the lowest ($P < 0.0045$) compared with the other four groups and no statistical difference in anaemia after intervention among the other four groups ($P > 0.05$) was observed with multiple comparative χ^2 tests.

Effects of intervention on serum biochemical indices and anthropometric measurements

The concentrations of serum retinol, Hb, PA and RBP and anthropometric measurement Z-scores, including HAZ, WAZ and WHZ, at baseline and at the end of the

study, as well as the change over 3 or 9 months of intervention, are summarised in Tables 3 and 4. At baseline, no significant difference in these indices was observed among the four groups ($P > 0.05$). After the 3-month supplementation, the concentrations of serum retinol, RBP, HAZ, WAZ and WHZ in all groups increased markedly compared with the baseline ($P < 0.05$), but those of PA and Hb increased only in groups II, III and IV. Meanwhile, the increase in serum retinol in children of group III was the highest compared with the other three groups, while that of group I was the lowest (both $P < 0.05$). No statistical difference in the change of serum retinol was found between the group II and group IV children ($P > 0.05$). Moreover, the increases in Hb, PA, HAZ and WHZ in group I were the lowest in comparison to the other three groups ($P < 0.05$) and there was no significant difference in the changes in Hb, PA, HAZ and WHZ among groups II, III and IV ($P > 0.05$). No significant difference in the changes in RBP and WAZ was observed among the four groups ($P > 0.05$).

*Data are presented as median (25th, 75th) as variables were non-normally distributed.

†Group I-3 and group I-9, 3- and 9-month follow-up of group I, respectively.

‡At baseline, no significant difference was observed among the four treatment groups ($P > 0.05$).

§SNK rank test or SNK test for multiple comparisons; within a row, unlike letters (A, B) indicate significant difference.

||After 3- or 9-month supplementation, the levels increased markedly compared with baseline.

WAZ and WHZ increased significantly after 9-month supplementation ($P < 0.05$). The changes in PA and Hb at the end of 9-month supplementation were the highest compared with the other four groups at the end of 3-month supplementation ($P < 0.05$), but the changes in RBP were the lowest ($P < 0.05$). The change in serum retinol was the same as that at the end of 3-month supplementation in group I (group I-3; $P > 0.05$). No significant changes in HAZ and WHZ at the end of 9-month supplementation were observed compared to groups II, III and IV ($P > 0.05$), but they were higher than that in group I-3 ($P < 0.05$). However, the levels in WAZ at the end of 9-month supplementation were similar to those of other groups ($P > 0.05$).

Discussion

In the present study, we found that the intervention of biscuits fortified with vitamin A at 100% of the RDA daily for 3 months had the same effect on the improvement of VAD, anaemia and physical growth and development as did the weekly 20 000 IU or single 200 000 IU administration in pre-school children in a suburb of Chongqing, China.

Effects of intervention on the prevalence of VAD and anaemia

Ethical consideration precluded the use of an unsupplemented placebo group; therefore we just used a positive-controlled strategy that enabled effective comparison

of the new, different doses of a vitamin A supplementation schedule on vitamin A and anaemia status.

This randomised double-masked population-based field interventional trial with a positive control group showed that providing lower doses through fortified biscuits provided daily or weekly was as efficacious in reducing the prevalence of VAD and anaemia as high-dose vitamin A administration. However, the present study did show the similar and greater efficacies of a daily low dose of vitamin A administration with extended duration in reducing the incidence of VAD and anaemia compared with the mass-dose vitamin A given. The major strength of the present study was the rigorous design and statistical analysis and the careful standardisation of the experimental measurement. To our knowledge, this is the first clinical trial to simultaneously exploit the effect of different doses of vitamin A intervention, including daily 30% RDA, daily 100% RDA, weekly 20 000 IU and single 200 000 IU, on the prevalence of VAD and anaemia in pre-school children.

The WHO recommends that vitamin A supplements should be given when children are vaccinated, and the currently recommended doses are 100 000 IU at the age of 6–11 months and 200 000 IU every 3–6 months at the age of ≥ 12 months⁽¹⁸⁾. There is no clear evidence, however, that a large dose is better than a smaller one. Serial population-based field trials^(19–23) have studied the effect of different administered doses of vitamin A on children's mortality and/or morbidity. Previous researches have

implied that a low dose of vitamin A could always lower the mortality or the morbidity of children compared with a high dose and that the effect of supplementation might not be exclusively due to the prevention of vitamin A deficiency⁽²⁴⁾. However, no integrated study has been performed to compare the effect of different doses of vitamin A supplements on the prevalence of VAD and anaemia in pre-school children, except for some researches about mass dose of vitamin A supplementation.

Recently, Darboe *et al.*⁽²⁵⁾ pointed out that no difference in serum retinol level was found as one of the primary outcomes for high-dose vitamin A *v.* the WHO schedule, while the trial had shown possible adverse effects of higher doses of vitamin A consistent with results from Been and colleagues⁽²³⁾. Another study⁽²²⁾ also proved that a low dose of vitamin A (22 500 IU) administered to infants is similar to substantially enhancing the biochemical vitamin A status of infants at the age of 6 months compared with a high dose of vitamin A supplement (45 000 IU) and some vitamin A capsules degraded towards the end of the study. Moreover, Sivan *et al.*⁽²⁶⁾ documented that administration of 10 ml red palm oil (including 800 retinol equivalent retinol) did not offer a substantial improvement in the serum retinol level over a 5 ml daily dose (including 400 retinol equivalent retinol). One study⁽²⁷⁾ reported that the intervention of a low dose of vitamin A did not improve the serum retinol status of children, but that was without any high-dose vitamin A intervention group for comparison. A similar research⁽²⁸⁾ study also indicated that a low-dose vitamin A supplementation had no effect on the increase of Hb response. Although a field trial⁽²⁹⁾ about vitamin A supplementation suggested that a high dose of vitamin A supplement could significantly improve serum retinol, mean Hb level and reduce the prevalence of anaemia compared with the control group, this trial lacked a low-dose vitamin A group as a control.

Our data indicated that the weekly administration of 20 000 IU of vitamin A supplement was most efficacious on the change of concentration of serum retinol. However, this dosage was also the most cumulative dose (240 000 IU in total) compared with the other groups and a long-term use of such dose might increase the risk of vitamin A toxicity. Though daily 30% RDA, 100% RDA and a single dose of 200 000 IU of vitamin A supplement had similar effects on the improvement of VAD, the former two supplement styles, based on the lower risk of toxicity of the RDA, might be the predominant doses for long-term intervention.

To our knowledge, there is no other study investigating the effect of different vitamin A supplement doses on vitamin A nutriture indicators, such as PA and RBP. In the present study, we found that the different doses of vitamin A had almost no effect on the concentrations of PA and RBP, suggesting that these indicators are buffered by the normal hepatic homeostatic regulation of retinol

stores and distribution, and hence are only effective at the extremes of vitamin A status. Nevertheless, they continue to be indicators of vitamin A status recommended by the WHO and the International Vitamin A Consultative Group⁽¹²⁾, and help to confirm that the population we studied had mild vitamin A deficiency, as evidenced by about 7.57% prevalence of values below 0.7 $\mu\text{mol/l}$ in pre-school children.

Remarkably, our findings were in partial agreement with some observations that single-dose supplements, repeated-dose supplements and high vitamin A intake do not alter retinol bioavailability; conversely, such intakes are associated with greatly increased exposure to toxic metabolites of vitamin A, such as retinyl palmitate, 13-*cis*-retinoic acid and 13-*cis*-4-oxo-retinoic acid⁽³⁰⁾. The well-known phototoxicity and photomutagenicity of these compounds, which are linked to the generation of reactive oxygen species⁽³¹⁾, could be of concern and osseous side-effects have also been shown in children and adults treated with 13-*cis*-retinoic acid⁽³²⁾.

Our data also indicated that the daily 30% RDA vitamin A with 9-month supplementation seemed to be more effective in decreasing the prevalence of anaemia and improving the Hb level. However, considering the various factors that might affect the results in the duration, such as the growth of the children with some possible changes in vitamin A and Hb status, diet and diseases, etc., we could not conclude whether 30% RDA vitamin A with 9-month intervention style was the best. Further studies are required to compare the effects of different doses of vitamin A intervention for a long equal duration, to approach a more prominent way to improve anaemia.

Effect of intervention on anthropometric measures

The results showed that compared with pre-treatment, linear growth was similarly increased significantly for all of the pre-school children in the five supplement groups. Therefore, fortified biscuits might not only prevent the deterioration of anthropometric status but also improve it. Comparisons did not show the additional effect of a mass dose of vitamin A on anthropometric measures when contrasted with weekly 20 000 IU and daily 100% RDA supplements. However, contrary to our data, some other studies have suggested that mass-dose vitamin A had no effect on children's anthropometry, growth velocity, Z-scores, or body composition compared with the placebo-controlled group⁽³³⁻³⁵⁾.

Measurement of the dose that gives the maximum reduction in the prevalence of VAD and anaemia and/or the increase of physical growth is difficult and without the knowledge of the mechanisms by which the reduction in VAD and anaemia is achieved, many large-scale empirical trials are needed. Potential adverse effects of vitamin A supplementation are difficult to predict and surrogate predictors might assist in tailoring supplementation in different environments.

There are some limitations in the current study. The effects of fortified biscuits on anthropometric status need to be investigated further and protective packaging of the biscuits for oral application must also be used. Furthermore, because of the limited design of the original protocol and the inadequate amount of blood samples obtained from these pre-school children, we did not simultaneously evaluate some other confounding factors, such as seasonal components and other essential nutrients (serum zinc, iron, or unsaturated fatty acid, etc.), which are capable of affecting anaemia and physical growth. Measuring these micronutrient levels will be an important aspect in future studies. In addition, regardless of the investigation of the regular consumption of milk, liver, egg and deep-coloured vegetables, we did not measure dietary intakes of nutrients by 24 h recall questionnaires, which might lead to insufficient evaluation of the effect of pre-school children's dietary habits on their nutritional and growth status.

In summary, our results indicate that consumption of vitamin A-fortified biscuits with daily 100% RDA for 3 months has the same effect on the improvement of VAD, anaemia and physical growth and development as did the weekly 20 000 IU or single 200 000 IU administration in pre-school children in a suburb of Chongqing, China.
