(Received 21 May 2001 – Revised 18 February 2002 – Accepted 12 March 2002)

Mice were deprived of food for a period of 72 h at varying times relative to the time of infection with *Paracoccidioides brasiliensis*. Host resistance was diminished profoundly when the period of food deprivation was from 48 h before to 24 h after infection (group B). When food deprivation was initiated immediately after infection (group C), host resistance was reduced less profoundly. When food deprivation was initiated at 24 and 48 h post-infection, reductions in host resistance were only moderate or not observed respectively. These results suggest that the earlier in the course of infection starvation occurs, the more profoundly host resistance is impaired. When food deprivation was initiated 72 h before infection, finishing at the time of infection (group A), the reduction in host resistance was considerably less profound compared with group B mice, suggesting that refeeding initiated immediately after infection is responsible for rapid restoration of the antifungal resistance in starved mice. Infection-induced responses of corticosterone and interferon- γ were changed according to the timing of food deprivation. Group A mice, similar to non-fasted controls, showed an infection-induced increase in serum corticosterone concentration, while groups B and C did not. Group C mice showed a substantially greater infection-induced increase in serum interferon- γ compared with the other fasted and non-fasted control groups.

Acute starvation: Infection: Interferon- γ : Corticosterone

It is well known that changes in nutritional state can alter immune responses and influence resistance to infection (Gordon & Ingalls, 1959; Gross & Newberne, 1980; Chandra, 1992). In both developing and advanced countries, acute starvation is an important public health problem that occurs in a variety of clinical and social settings. Fasting healthy human subjects for 7 d decreased peripheral blood mononuclear cell production of interleukin 2 in response to phytohaemagglutinin (Saevendahl & Underwood, 1997). On the other hand, it was reported that acute starvation increased macrophage activity in mice (Wing *et al.* 1983). However, the mechanisms underlying the effect of starvation on host resistance still remain to be fully defined.

Paracoccidioides brasiliensis is the causative agent of paracoccidioidomycosis, the most prevalent human systemic mycosis in Latin American countries. Although it has been documented that protection against *P. brasiliensis* in mice is dependent upon cellular immunity (Franco, 1987), there has been no investigation concerning the

specific antifungal mechanisms that might be compromised in acute starvation. In an effort to obtain information regarding the mechanisms, we investigated the effect of different timings of 72 h food deprivation relative to the time of infection on host resistance against *P. brasiliensis* in mice.

Materials and methods

Fungi

P. brasiliensis isolate Pb-18, isolated from a Brazilian patient with paracoccidioidomycosis, was employed for infecting mice. Cells of the fungus used in the experiments were newly derived from the mycelial form and subcultured twice at 35°C at 4 d intervals on glucose-supplemented (10 g/l) brain–heart infusion (Difco Laboratories, Detroit, MI, USA) agar slants. Fresh growth (4 d) of the fungus was collected in sterile saline (9 g/l) and passed through a wire mesh to eliminate clumps of fungal cells. After

Abbreviations: ACTH, adrenocorticotrophic hormone; CFU, colony-forming units; IFN, interferon.

washing once, fungal cells were counted with a haemocytometer. More than 97% of the fungal cell units thus prepared were viable (Kurita *et al.* 1993). Fungal cells were resuspended at desired densities in saline for infecting mice.

Experimental infections

Specific-pathogen-free 6-week-old female BALB/c mice were obtained from Charles River Japan (Atsugi, Japan), and were maintained at 23°C on a 12 h light–dark cycle (light on 07.00 hours) and allowed free access to standard non-purified MF diet (Oriental Yeast Inc., Osaka, Japan) and water. Mice at the age of 7 weeks were infected by injecting once with 200 µl fungal cell suspension (1×10^7 cells/ml) intravenously via the lateral tail vein at 11.00 hours. Groups of mice were deprived of food for a period of 72 h at varying times relative to the time of infection as illustrated in Fig. 1. Food deprivation was started at 11.00 hours in all the groups. During the period of food deprivation, mice were allowed free access to water. Mice were killed under diethyl ether anaesthesia at 11.00 hours on days 1–7 post-infection, and blood, spleen and liver were harvested.

The present experiments were performed according to The Guide for the Care and Use of Laboratory Animals (1985) of The National Institute of Health and were approved by The Committee of The Chiba University for Experimental Animals.

Counts of viable fungal cells from organs

Whole spleens and livers were aseptically removed from mice and homogenized in a glass homogenizer with 4 and 19 ml saline respectively, and samples were diluted with saline. Then, 1 ml of the dilution was plated on brain–heart infusion (Difco Laboratories) agar supplemented with 50 µmol EDTA/l, 20 ml horse serum/l (Gibco Laboratories, Grand Island, NY, USA) and

150 µmol chloramphenicol/l (Wako Pure Chemical Industries, Osaka, Japan). The agar plates were incubated in a humidified atmosphere at 35°C, and the colony-forming units (CFU) of *P. brasiliensis* were counted after 12 d incubation.

Interferon- γ assay

Blood was collected by cardiac puncture and allowed to clot for 40 min at room temperature. Serum was then separated by centrifugation at 3000 g for 20 min at 4°C. Portions of serum samples were stored at –80°C until interferon (IFN)- γ analysis. Spleens and livers were rapidly removed from mice, weighed, placed in cold RPMI 1640 medium, and homogenates (100 g/l) were prepared with a glass homogenizer. The homogenates were subjected to two cycles of freeze-thawing, and then were clarified by centrifugation at 9000 g for 45 min at 4°C. The supernatant fractions were assayed for IFN- γ .

The concentrations of IFN- γ in sera and in tissue extracts were determined by an ELISA method using a commercial kit (Amersham International, Amersham, Bucks, UK). Assays were carried out in duplicate and the averages of the individual data were statistically analysed.

Assays of serum corticosterone and adrenocorticotrophic hormone

Mice were killed by decapitation between 10.30 hours and 11.00 hours on days 1–7 post-infection and blood was collected. Sera were prepared and stored at –80°C until analysed. Serum corticosterone and adrenocorticotrophic hormone (ACTH) concentrations were determined using a radioimmunoassay kit (ICN Biomedical, Costa Mesa, CA, USA) and an enzyme immunoassay kit (Peninsula Laboratories, Belmont, CA, USA) respectively (Espey & Basile, 1999). Serum samples were heated to 85°C for 15 min prior to analysis of corticosterone to prevent proteolytic interference during radioimmunoassay incubation (Jessop *et al.* 1987). All assays were carried out in duplicate and the averages of the individual data were statistically analysed.

Statistical analysis

All data are expressed as mean values with their standard deviations for *n* observations and statistically evaluated by ANOVA with the SPSS computer programs (release 6.1; SPSS Japan Inc., Tokyo, Japan). Changes in CFU count of *P. brasiliensis* from spleen and liver, and infection-induced changes in IFN- γ concentration were evaluated by two-way ANOVA. For corticosterone and ACTH concentrations data, values were analysed by three-way ANOVA. Turkey-HSD tests were used for *post-hoc* analysis. The level of significance was set at $P < 0.05$.

Results

Effect of fasting on antifungal resistance

the mice in groups A, B, C, D and E were reduced to 75.4, 77.6, 78.6, 77.3 and 79.7% of those at the beginning of food deprivation respectively, and returned to the level of the non-fasted control group after 2–3 d of refeeding.

The CFU counts recovered from spleen and liver were taken as a measure of the host resistance to infection. The CFU count at day 0 was determined at 2 h after inoculation. In the non-fasted control group, group A, group D and group E, the spleen CFU count did not vary significantly during the first 2, 3, 4 and 2 d of infection respectively, and thereafter decreased progressively (Table 1). In contrast, in the spleen of groups B and C, the CFU increased, peaking at day 3 post-infection; percentage increase above CFU at day 0 was greater in group B than group C (275 v. 189% at day 3). These results indicate that resistance of the spleen is reduced more profoundly in groups B and C than group A, D or E and that the reduction is more profound in group B than group C. In the liver, the CFU count in all the fasted groups and in the non-fasted control group increased, peaking at day 3 or 4 post-infection (Table 2). In group A, the percentage increase in the liver CFU was greater than that of the non-fasted control group (213 v.

136% at day 4), but smaller than that of group B (213 v. 322% at day 4). Percentage increase in the liver CFU was greater in group B than group C (359 v. 255% at day 3). The increase in CFU count in group D was less than that of group B (230 v. 359% at day 3). In group E, compared with non-fasted controls, no significant reduction in the host resistance was observed both in the spleen and liver.

Effect of fasting on interferon- γ response to infection

Since IFN- γ is a major mediator of host resistance against *P. brasiliensis* infection in mice (Cano *et al.* 1998), the effect of fasting on the infection-induced IFN- γ response was investigated. Group C mice showed a substantially greater increase in serum IFN- γ concentration between day 3 and 4 compared with the non-fasted control group (Table 3). In contrast to group C, in groups A, B, D and E the overall increase in serum IFN- γ concentration (during the first 7 d of infection) was not markedly different from that of the non-fasted control group.

Group C mice also showed a considerably greater increase in spleen IFN- γ concentration between day 3

and 5 compared with the non-fasted control group (Table 4).

In the liver, IFN- γ constitutively existed at a concentration of 3.2–4.8 ng/g wet tissue. In all groups, including the non-fasted control group, the liver IFN- γ concentration increased to 7.8–9.5 ng/g wet tissue by day 3 after infection, stayed at an elevated concentration until day 5, and then returned to the basal concentration by day 7 (results not shown).

Effect of fasting on corticosterone and adrenocorticotrophic hormone responses during infection

Glucocorticoids have been well documented to be involved in suppression of inflammation and immune reactions (Munck *et al.* 1984). It is well known that treatment with glucocorticoids increases vulnerability to infections. The serum glucocorticoid concentration is known to increase in response to various factors, including fasting (Millward *et al.* 1983; Mitev *et al.* 1993) and infections (Zhang *et al.* 1998). In all the fasted groups, the serum corticosterone concentration increased due to the 72 h fasting process (Table 5), and returned to the pre-fasting level within 1 h after initiation of refeeding (results not shown). In group A mice, like non-fasted controls, the serum corticosterone concentration increased in response to infection, peaking at day 4 post-infection. In contrast, an infection-induced increase in the serum corticosterone did not occur in groups B and C. In groups D and E, day 4 of infection overlapped the fasting period. In these groups, the infected mice did not show a greater increase in serum corticosterone concentration compared with non-infected mice.

Table 6 shows variation of the serum ACTH concentration in response to fasting and infection. Mice in all the fasted groups had an increased serum ACTH concentration during the 72 h fasting period. The fasting-induced increase in ACTH concentration was reversed within 1 h of initiation of refeeding (results not shown). Non-fasted control mice showed an infection-induced increase in the serum ACTH concentration (1.50 ng/ml serum at day 5 post-infection), while groups A, B, C and D did not. In group E, day 5 of infection overlapped the fasting period. In this group, the infected mice did not show a greater increase in serum ACTH concentration compared with non-infected mice.

Discussion

The present study revealed that difference in timing of starvation and refeeding relative to the time of infection is responsible for a substantial variation in host resistance. Fasted mice in group C showed greater spleen IFN- γ production (Table 4) and higher serum IFN- γ concentrations (Table 3) in response to infection compared with the non-fasted control group, while their host resistance was reduced (Tables 1 and 2). The reason for the greater IFN- γ production in group C mice is unclear. It has been reported that overproduction of IFN- γ is responsible for increased lethality of *Candida albicans*-infected mice (Lavigne *et al.* 1998), and that treatment with anti-IFN- γ antibody improves the survival of mice infected with

gram-negative bacteria (Kohler *et al.* 1993). Thus, the greater IFN- γ response of group C mice could be more detrimental to the host compared with the case of the non-fasted control group, although it might simultaneously contribute to host resistance against *P. brasiliensis*. It is well known that the rate of biosynthesis and/or release of various hormones and neuropeptides vary rapidly in response to starvation and refeeding. Beer *et al.* (1989) have reported that, in human subjects, plasma cortisol, ACTH, β -endorphin and adrenaline concentrations increase, and plasma insulin concentration decreases, within 9 h after initiation of 72 h starvation, returning to or near pre-starvation concentration within 6 h after initiation of refeeding. Millward *et al.* (1983) have shown in rats that change in plasma corticosterone and insulin concentrations due to 4 d food deprivation return to the pre-fasting level within as little as 40 and 180 min of initiation of refeeding respectively. On the other hand, it has been well documented that various hormones and neuropeptides, as well as cytokines, are able to influence immunological activities and also host resistance (Blalock, 1989). Thus, it is assumed that variation in host resistance due to different timings of acute starvation (and refeeding) is, at least partly, associated with rapid changes in the rate of synthesis and release of certain hormones and/or neuropeptides. Group A mice, in which 72 h starvation was finished at the time of infection and refeeding was initiated immediately after infection, showed a less profound reduction in host resistance compared with group B, in which infection was initiated at 48 h time point of 72 h starvation (Tables 1 and 2). In group A mice, serum corticosterone and ACTH concentrations returned rapidly to the pre-fasting levels within 1 h of infection due to refeeding, which commenced at the same time as infection. This may, at least partly, account for the only moderate reduction in host resistance of these mice. In group B, the last 24 h of the 72 h fasting period overlapped the first 24 h of infection (Fig. 1). Thus, increased serum corticosterone and ACTH concentrations persisted throughout the first 24 h of infection (Tables 5 and 6). Group C mice showed a less profound reduction in host resistance than group B mice. In group C mice, the serum corticosterone and ACTH concentrations were as low as those of the non-fasted control group during the first 4–6 h of infection (results not shown). The different pattern in corticosterone and ACTH concentrations during the initial stage of infection between groups B and C may, at least partly, account for the more profound reduction in host resistance in the former than the latter group (Tables 1 and 2). Group E mice, in which the fasting was initiated 48 h after infection, showed no significant reduction in host resistance compared with the non-fasted control group. Taken together, our results suggest that if infection occurs during a period of elevation of glucocorticoid concentration due to starvation, then host resistance is profoundly impaired. Since starvation and refeeding could influence responses of not only glucocorticoids and ACTH but also other hormones and neuropeptides (Millward *et al.* 1983; Beer *et al.* 1989), the mechanisms underlying the variation in host resistance due to different timings of acute starvation remain to be further investigated.

a,b,c,d,e,f,g Mean values with unlike superscript letters were significantly different ($P < 0.05$).

* For details of procedures, see p. 152.

† Time post-infection (d).

‡ For details of treatment of each group, see Fig. 1.

§ Mice were injected with saline with (+) or without (-) fungal cells at day 0 (for details see p. 152).

Food deprivation and fungal infection

ACTH, adrenocorticotrophic hormone.

^{a,b,c,d,e}Mean values within a column with unlike superscript letters were significantly different ($P < 0.05$).

* For details of procedures, see p. 152.

† Time post-infection (d).

‡ For details of treatment of each group, see Fig. 1.

§ Mice were injected with saline with (+) or without (-) fungal cells at day 0 (for details see p. 152).
