#### The Importance of Environmental Screening in a Methicillin-Resistant *Staphylococcus aureus* (MRSA) Outbreak Investigation in a Transplant Unit

Xiang Ying Jean Sim, Singhealth; Moi Lin Ling, Singapore General Hospital; Indumathi Venkatachalam, Singapore General Hospital (SGH)

**Background:** Methicillin-resistant *Staphylococcus aureus* (MRSA) colonization conveys a higher risk of invasive infection. The transplant cohort is a group of immunocompromised patients who are at higher risk of infection. We conducted an outbreak investigation of hospital-acquired MRSA colonization within the transplant unit, which led to the discovery of positive isolates within our environment and to changes in our hospital disinfection policies. **Methods:** Our transplant unit consists of 8 single, positive-pressure rooms housed separately at the side of a larger ward. Staffing from this unit differs from the rest of the shared ward that houses up to 60 patients. As part of hospital screening, we found that a patient admitted for a stem-cell transplant had acquired nosocomial MRSA colonization. Given the unusual occurrence of such an event, a root-cause analysis was conducted. **Results:** A meeting was convened together with nursing, medical staff, and ancillary staff. Identified areas of potential transmission were deemed equipment, staff, and patients, and screening was performed. Shared equipment included the portable electrocardiogram (ECG) machines and portable x-ray machines and boards. In particular, ECG machines were shared with the adjoining non-transplant oncology ward. The usual practice was to clean the machine after use but not prior to the next use. This was deemed a possible exposure risk in view of a recent MRSA outbreak in a separate section of the ward. Positive isolates were found on both the x-ray and ECG machines. All healthcare workers were screened and were negative for MRSA. Furthermore, 7 patients admitted during the same time period were also screened for MRSA and were

**Table 1.** Summary of Screening Results

Category	No. Screened	Positive Screens
ECG machines	2	1
X-ray machines	2	1
X-ray plates	2	0
Nurses	29	0
Doctors	9	0
Radiology staff	10	0
Housekeeping staff	8	0
Patients	7	0
Total	69	2

negative. Given the concurrent outbreak within the ward, pulsed-field gel electrophoresis was performed for all MRSA isolates obtained and the outbreak strain. These were found to be nonclonal (Table 1). Work processes for both the cleaning of ECG and x-ray machines were enhanced and modified. Hand hygiene measures to ward and radiology staff were reinforced. Thus far, no further cases have been detected. **Conclusions:** The environment is an important part of outbreak investigation. Shared equipment is often overlooked during day to day processes but should not be neglected. This can result in changes to hospital disinfection policy.

#### The Second Central Line Increases Central-Line-Associated Bloodstream Infection Risk by 80%: Implications for Inpatient Quality Reporting Programs

William Dube, Emory University School of Medicine; Jesse Jacob, Emory University; Ziduo Zheng, Emory University Rollins School of Public Health; Yijian Huang, Emory University Rollins School of Public Health; Chad Robichaux, Emory University; James Steinberg, Emory University; Scott Fridkin, Emory Healthcare and Emory University

**Background:** The NHSN methods for central-line-associated bloodstream infection (CLABSI) surveillance do not account for additive CLABSI risk of concurrent central lines. Past studies were small and modestly risk adjusted but quantified the risk to be ~2-fold. If the attributable risk is this high, facilities that serve high-acuity patients with medically indicated concurrent central-line use may disproportionately incur CMS payment penalties for having high CLABSI rates. We aimed to build evidence through analysis using improved risk adjustment of a multihospital CLABSI experience to influence NHSN CLABSI protocols to account for risks attributed to concurrent central lines. **Methods:** In a retrospective cohort of adult patients at 4 hospitals (range, 110–733 beds) from 2012 to 2017, we linked central-line data to patient encounter data (age, comorbidities, total parenteral nutrition, chemotherapy, CLABSI). Analysis was limited to patients with >2 central-line days, with either a single central line or concurrence of no more than 2 central lines where insertion and removal dates overlapped by >1 day. Propensity-score matching for likelihood of concurrence and

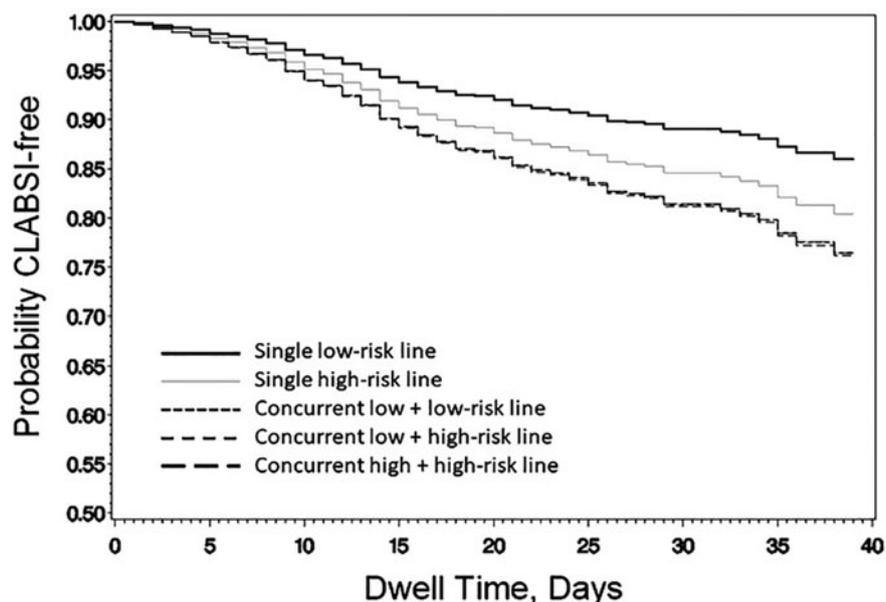

Fig. 1

conditional logistic regression modeling estimated the risk of CLABSI attributed to concurrence of >1 day. To evaluate in Cox proportional hazards regression of time to CLABSIs, we also analyzed patients as unique central-line episodes: low risk (ie, ports, dialysis central lines, or PICC) or high risk (ie, temporary or nontunneled) and single versus concurrent. **Results:** In total, 64,575 central lines were used in 50,254 encounters. Among these patients, 517 developed a CLABSI; 438 (85%) with a single central line and 74 (15%) with concurrence. Moreover, 4,657 (9%) patients had concurrence (range, 6%–14% by hospital); of these, 74 (2%) had CLABSI, compared to 71 of 7,864 propensity-matched controls (1%). Concurrence patients had a median of 17 NHSN central-line days and 21 total central-line days. In multivariate modeling, patients with more concurrence (>2 of 3 of concurrent central-line days) had a higher risk for CLABSI (adjusted risk ratio, 1.62; 95% CI, 1.1–2.3) compared to controls. In survival analysis, 14,610 concurrent central-line episodes were compared to 31,126 single low-risk central-line episodes; adjusting for comorbidity, total parenteral nutrition, and chemotherapy, the daily excess risk of CLABSI attributable to the concurrent central line was ~80% (hazard ratio 1.78 for 2 high-risk or 2 low-risk central lines; hazard ratio 1.80 for a mix of high- and low-risk central lines) (Fig. 1). Notably, the hazard ratio attributed to a single high-risk line compared to a low-risk line was 1.44 (95% CI, 1.13–1.84). **Conclusions:** Since a concurrent central line nearly doubles the risk for CLABSI compared to a single low-risk line, the CDC should modify NHSN methodology to better account for this risk.

#### Trends of Adult Antimicrobial Hospital Consumption in Catalonia (Spain) from 2008 to 2018

Santiago Grau, Hospital del Mar; Sergi Hernández, VINCAT Program Surveillance of healthcare related infections in

Catalonia; Ariadna Padullés, Hospital Pharmacist; Montserrat Gimenez, Microbiology Service Ricard Ferrer, Hospital vall d'Hebron; Lucía Boix-Palop, Infectious Diseases Unit, Internal Medicine Department, Hospital Universitari Mútua Terrassa; Susana Melendo, Pediatric Infectious Diseases and Immunodeficiencies Unit, Hospital Universitari Vall d'Hebron; Glòria Oliva, Departament de Salut. Generalitat de Catalunya Esther Calbo, Hospital Universitari Mútua Terrassa; Juan P. Horcajada, Department of Infectious Diseases. Hospital del Mar

**Background:** Antimicrobial resistance is a disturbing problem in the health system. A relationship between the use of certain antimicrobials and a resistance increase has been proposed. Since this phenomenon is not usually attributed to specific uses of antimicrobials but preferably to its evolution over the years, the analysis of the antimicrobial consumption over time can justify the epidemiological situation of a given region in terms of resistance and possible increases and decreases for specific microorganisms. The objective of this study was to analyze the evolution of the use of antimicrobials in Catalonia during 2008–2018 through the VINCAT program (Infection Control and Antimicrobial Stewardship Catalan Program). **Methods:** The number of hospitals participating in the VINCAT increased from 46 in 2008 to 63 in 2018 (ie, 68.8% and 85.7% of all adult acute-care hospital beds in Catalonia, respectively). Hospitalization days recorded at the participating hospitals increased from 2,991,053 in 2008 to 3,714,938 in 2018. The Anatomical Therapeutic Chemical Classification (ATC) defined daily dose (DDD) index was used for monitoring antimicrobial consumption. Simple linear regressions were performed, the linear relationship was checked by ANOVA tests, and the Pearson correlation ( $P_c$ ) coefficients were obtained. Values of  $P \leq .05$  were considered statistically significant. **Results:** From 2008 to 2018, there was a statistically significant increase of global antibacterial consumption (65.50 vs 71.73 DDD per 100 bed days;  $P = .001$ ) and antimycotic consumption (3.09 vs 3.45 DDD per 100 bed days,  $P = .012$ ) due to an increase of consumption in the surgical units. At the same time, there was a decrease in the consumption of antimycotics in the medical units (4.35 vs 3.90 DDD per 100 bed days;  $P = .029$ ).
