There is much interest in nanoscale materials due to their size-dependent properties, including variations in electronic bandgap, photoluminescence, and catalytic activity [1-4]. Platinum nanoparticles are of particular interest due in large part to their catalytic activity and potential applications in fuel cells. It has been shown that several factors affect the behavior of platinum nanoparticles as catalysts, including synthesis technique, size, and substrate material [5-7]. A means to isolate individual nanoparticles for characterization is therefore desirable. In this paper a technique for synthesis of isolated platinum nanocrystals is reported. The substrates used in this study (ultra-sharp aluminum *needles*) have the advantage of requiring no further sample preparation for observation in a transmission electron microscope. Preliminary characterizations were conducted, including x-ray energy-dispersive spectroscopy (EDS), transmission electron microscopy (TEM), and electron energy loss spectrometry (EELS).

Electrochemically etched aluminum *needles* were employed as substrates for the platinum nanocrystal synthesis. The etching process of the aluminum is described briefly: 99.999% aluminum wire (150 μm diameter) was biased (15-20 VAC) in a 20% perchloric acid (in methanol) solution at -30°C; the wire was etched until breaking, resulting in a pointed *needle* with a radius of curvature ~50nm. The electrode used in the acid bath was a platinum wire (250 μm diameter, 99.99%), which served as a source for platinum deposition onto the aluminum needle. Subsequent to etching and after undergoing field electron emission (experiments for which the sample was originally intended), it was discovered that the aluminum needle contained platinum nanocrystals on the surface (Figures 1 and 2). A mechanism for platinum deposition is proposed, which consists of: 1) the dissolution of the platinum electrode in solution, forming the PtCl₆²⁻ complex and 2) the plating out of the Pt⁴⁺ ion onto the aluminum during the negative half-cycle of the AC etching process. Field emission is thought to play a crucial role in nanocrystal formation; the high electric fields (~10⁷V/cm) and current densities (~10⁶A/cm²) are believed to facilitate surface migration and crystallization of the *plated* platinum. To support the proposed mechanism, a set of samples was etched with varying conditions: AC, *pulsed* DC (half-wave rectified AC), and AC followed by *pulsed* DC, and then analyzed using x-ray energy dispersive spectroscopy; the results are summarized in Table 1. Further studies are underway to better understand this phenomenon.

TABLE 1. Summary of aluminum etching conditions and corresponding platinum deposition.

Etching Conditions	Platinum Present
AC (15-20 V)	Yes
Pulsed DC (1/2 wave rectified AC)	No
AC followed by Pulsed DC	No
