Abstract

Ion homeostasis is a crucial process in plants that is closely linked to the efficiency of nutrient uptake, stress tolerance and overall plant growth and development. Nevertheless, our understanding of the fundamental processes of ion homeostasis is still incomplete and highly fragmented. Especially at the mechanistic level, we are still in the process of dissecting physiological systems to analyse the different parts in isolation. However, modelling approaches have shown that it is not individual transporters but rather transporter networks (homeostats) that control membrane transport and associated homeostatic processes in plant cells. To facilitate access to such theoretical approaches, the modelling of the potassium homeostat is explained here in detail to serve as a blueprint for other homeostats. The unbiased approach provided strong arguments for the abundant existence of electroneutral H⁺/K⁺ antiporters in plants.

1. Introduction

Homeostasis is the ability of an organism to maintain stable physico-chemical conditions that are compatible with cell metabolism despite fluctuations in the external environment. Plants are subject to permanent changes in the availability of water, nutrients and light energy as well as other parameters, such as temperature, which influence the entire metabolism. Plants are a semi-open system in which the concentrations of apoplastic fluid vary and depend on environmental parameters, in particular, the water potential of the soil and the concentration of dissolved substances, on the one hand, and on internal factors, such as stomatal conductance, on the other. Ion homeostasis is central to plant physiology as it regulates and maintains cell turgor, energises and controls nutrient flux (especially of sugars and amino acids) and is at the heart of numerous signalling pathways dependent on Ca²⁺ and H⁺. Each individual plant cell contributes to ion homeostasis by maintaining the concentrations of free ions in the syncytium and tissues that are optimal for growth and efficient ion-dependent signalling. Given the importance of ion homeostasis, understanding the mechanisms involved is crucial for improving crop yields and for developing strategies to cope with environmental stresses such as drought and nutrient deficiency.

Ion homeostasis involves the transport and sequestration or release into or out of various compartments such as apoplast, cytosol, vacuole, mitochondria, plastids, endocytic and exocytic membrane complexes. All these membranes have their own specific transporters and associated regulatory factors (regulatory proteins, voltage, pH, pCa, etc.) that form a highly complex system. Before approaching such complexity, a first step towards understanding the principles of ion homeostasis in plants can be a theoretical approach, looking at the simplest possible system and

Figure 1. The K homeostat. The K homeostat is a network of transporters that transport K⁺, in combination with the energising proton ATPase. It consists of H⁺ ATPases (pump), H⁺/K⁺ antiporters (H/Ka), H⁺/K⁺ symporters (H/Ks) and K⁺ channels (KC), which are embedded in a membrane that separates an internal compartment (*inside*) from an external compartment (*outside*). The system is determined by 12 parameters: Three of them (*white*) are determined by the geometry of the system: internal volume (Vol_{in}), external volume (Vol_{out}) and the membrane capacitance (C). Four of them (*grey*) describe the activity of the transporters: activity of the pump (*act. pump*), the antiporter (*act. H/Ka*), the symporter (*act. H/Ks*) and the K⁺ channel (*act. KC*). Two of them ($[H^+]_{in}$ and $[H^+]_{out}$, *light yellow*) are partially influenced by buffer reactions and transport processes different from the K homeostat. The remaining three ($[K^+]_{in}$, $[K^+]_{out}$ and V , *yellow*) depend on the setting of the K homeostat and are controlled by it.

searching for emergent properties. Over the last four to five decades, our knowledge of plant membrane transport has improved considerably thanks to the development of new techniques and molecular genomic analyses (Anschütz et al., 2014; Blatt, 2024; Hedrich, 2012; Jegla et al., 2019; Stanton et al., 2022; Ward et al., 2009) and physiological data that enable such a theoretical approach. Nevertheless, membrane transport in plants is still widely analysed using more than 70 years old concepts. For instance, the classification of transporters as ‘high-affinity’ and ‘low-affinity’ transporters was very helpful in the 1950s and 1960s in identifying different transporters *in vivo* and distinguishing between them (Epstein et al., 1963; Epstein & Hagen, 1952). However, the categorisation into these two groups and the interpretation that transporters with ‘high affinity’ are active at low concentrations, while transporters with ‘low affinity’ take over at higher concentrations, led to unclear conclusions and even contradictions (for further details, please see Dreyer, 2017; Dreyer & Michard, 2020). It became evident that there is an urgent need for a new solid theoretical foundation that not only describes the observed phenomena, but can also clearly explain them based on first principles. One such approach resulted in the theory of homeostats (Dreyer, 2021a), that is, transporter networks that act together and exhibit dynamic properties as a system that go beyond those of the isolated transporters (Dreyer et al., 2022; Li et al., 2024). This unbiased, systemic approach combines thermodynamics with biophysics and translates biological phenomena into the language of mathematics, enabling the derivation of analytical solutions or computational simulations of specific situations.

To increase the understanding and accessibility of such an approach, this article intends to serve as a hands-on tutorial for modelling a homeostat using the example of the potassium (K) homeostat. The transporter network of the K homeostat is composed of K⁺ channels, H⁺/K⁺ symporters, H⁺/K⁺ antiporters and H⁺-ATPases establishing the necessary proton and voltage gradients that energise the different transport processes (Figure 1).

Table 1. Parameters of the K homeostat system

Internal compartment	<ul style="list-style-type: none"> Vol_{in} (pL): internal Volume $[K^+]_{in}$ (μM): internal K⁺ concentration $[H^+]_{in}$ (μM): internal proton concentration
Membrane	<ul style="list-style-type: none"> C (pF): Membrane capacitance V (mV): membrane voltage Activity of H⁺-ATPases* Activity of K⁺ channels* Activity of H⁺/K⁺ symporters* Activity of H⁺/K⁺ antiporters*
External compartment	<ul style="list-style-type: none"> Vol_{out} (pL): external volume $[K^+]_{out}$ (μM): external K⁺ concentration $[H^+]_{out}$ (μM): external proton concentration
Derived parameters	<ul style="list-style-type: none"> $E_K = \frac{RT}{F} \cdot \ln \left(\frac{[K^+]_{out}}{[K^+]_{in}} \right)$ (Nernst potential for K⁺; mV) $E_H = \frac{RT}{F} \cdot \ln \left(\frac{[H^+]_{out}}{[H^+]_{in}} \right)$ (Nernst potential for H⁺; mV)

Note: The list of parameters determines the system of a K homeostat embedded in a membrane that separates two compartments. Appropriate definitions for the parameters marked with an asterisk (*) will be provided in the course of this study.

The system, in which the K homeostat is embedded, is a membrane that separates two compartments (internal/inside and external/outside) and is characterised by the following parameters (Table 1): volumes of the internal and external compartment (Vol_{in} , Vol_{out}), proton and potassium concentrations in the internal and external compartment ($[H^+]_{in}$, $[H^+]_{out}$, $[K^+]_{in}$, $[K^+]_{out}$), the membrane capacitance and membrane voltage (C , V), as well as the activities of the transporters.

By having chosen the K homeostat, we follow a historical pattern, because research on K⁺ transport in plants has been a constant driving force in the past for progress in membrane transport and has influenced research on nutrient transport in general (Britto et al., 2021; Dreyer, 2021b). We start with explaining the mathematical description of transmembrane transport processes through the different transporters. Then we present the differential equations that describe the changes in concentrations and the membrane voltage due to the transport processes. Thereafter, we analyse the system in a steady state. In a follow-up study, we will consider deviations from the steady state condition in order to get an idea about the dynamic properties of the homeostat. The different steps can in principle be applied to any other homeostat, as recently demonstrated for the auxin homeostat in plants (Geisler & Dreyer, 2024).

2. Methods

2.1 Mathematical description of transport processes

A theoretical/mathematical description of membrane transport requires to quantify the transport processes involved. For this purpose, the biophysical knowledge on transport (Hille, 2001) needs to be translated into the universal language of mathematics. Here, only basic knowledge on the membrane transport is often sufficient to obtain rather simple but very powerful equations. The art of mathematical modelling lies in the elimination of redundancies, which means that many physiological parameters can be combined

Figure 2. Modelling of fluxes through a transporter in a steady state. (a) The flux curve of a transporter $J_X(V)$ (grey line) is zero at $V = E_X^{ss}$ ($J_X(E_X^{ss}) = 0$, blue point). (b) In a steady state, flux and voltage are constant, and the curve is represented by the red point ($V_{ss}|J_X^{ss}$). The abscissa of this point is V_{ss} , while the ordinate, J_X^{ss} , can be expressed as $m \cdot (V_{ss} - E_X^{ss})$ using triangulation ($m = \tan(\alpha)$). (c) Changes in the activity are mirrored by changes in the slope m and the angle α . An increase in the transporter activity (dashed grey line), for example, by a higher expression or activation by phosphorylation, results in a larger J_X^{ss} -value (purple point), which is represented by a larger angle ($\alpha 1$) and hence a larger slope ($m1$). A decrease in transporter activity (dotted grey line), on the other hand, results in a smaller J_X^{ss} -value (pink point), smaller angle ($\alpha 2$) and smaller slope ($m2$). Thus, the slope m contains the regulatory features of the transporter.

into a few, non-redundant model parameters. As this manuscript will illustrate, such steps simplify both the equations and the computational handling of the model. However, in order to draw conclusions from the model calculations, the model output must be translated from mathematical language to biology. The challenge in understanding and the art of physiological interpretation lies particularly in the fact that independent physiological parameters in biology can be redundant in mathematics. Having this in mind, we may now tackle the question:

How can the net fluxes through a membrane transporter in a steady state be described?

Steady state corresponds to the state in which the system does not change any longer. Indeed, homeostatic conditions are steady state conditions because the system exhibits a certain stability and maintains its parameters constant. The homeostatic properties of a system can be analysed in a two-step process. First, the steady state is analysed and then, in the second step, the system is destabilised in order to investigate its resilience. In this study, we begin with the first step and will present the second in a follow-up paper.

In the beginning, we consider passive or secondary active transporters, that is, membrane proteins that do not couple ATP hydrolysis to transport activity (pumps will be considered later). The flux through a passive transporter (J_X) depends on the electrochemical gradient ($\Delta\mu$) of the transported solute across the membrane (Kedem & Katchalsky, 1963). For a permeating substrate X, this gradient is given by:

$$\Delta\mu_X = \mu_X^{\text{in}} - \mu_X^{\text{out}} = RT \cdot \ln([X]_{\text{in}}) + z_X F \psi_{\text{in}} - RT \cdot \ln([X]_{\text{out}}) - z_X F \psi_{\text{out}} = F \cdot \left(z_X V - \frac{RT}{F} \cdot \ln\left(\frac{[X]_{\text{out}}}{[X]_{\text{in}}}\right) \right), \quad (1a)$$

with the gas constant R , the Faraday constant F , the absolute Temperature T , the internal and external electrical potentials ψ_{in} and ψ_{out} ($\psi_{\text{in}} - \psi_{\text{out}} = V$, the membrane voltage), the valence z_X and the concentrations $[X]_{\text{in}}$ and $[X]_{\text{out}}$, of the substrate X, respectively (Carpaneto et al., 2005; Gerber et al., 2016; Nour-Eldin et al., 2012). The net flux of X through the transporter (J_X) is a function of the gradient $\Delta\mu_X$, that is, the concentrations and, if $z_X \neq 0$, also the membrane voltage. If the gradient is zero, $\Delta\mu = 0$, there is no net flux, that is, $J_X = 0$. Thus, if J_X depends on the membrane voltage, it is

zero at $V = E_X$, with $E_X = \frac{RT}{z_X F} \cdot \ln\left(\frac{[X]_{\text{out}}}{[X]_{\text{in}}}\right)$, also known as the Nernst (or zero-flux) potential for X. Otherwise, it is zero if $[X]_{\text{out}} = [X]_{\text{in}}$.

In the case of a secondary active co-transporter that transports n_X molecules/ions of type X (valence z_X) along with n_Y molecules/ions of type Y (valence z_Y), the electrochemical gradient is given by:

$$\Delta\mu_{XYs} = n_X \cdot \Delta\mu_X + n_Y \cdot \Delta\mu_Y = F \cdot \left[(n_X z_X + n_Y z_Y) \cdot V - n_X \frac{RT}{F} \cdot \ln\left(\frac{[X]_{\text{out}}}{[X]_{\text{in}}}\right) - n_Y \frac{RT}{F} \cdot \ln\left(\frac{[Y]_{\text{out}}}{[Y]_{\text{in}}}\right) \right], \quad (1b)$$

for a symporter, and by

$$\Delta\mu_{XYa} = n_X \cdot \Delta\mu_X - n_Y \cdot \Delta\mu_Y = F \cdot \left[(n_X z_X - n_Y z_Y) \cdot V - n_X \frac{RT}{F} \cdot \ln\left(\frac{[X]_{\text{out}}}{[X]_{\text{in}}}\right) + n_Y \frac{RT}{F} \cdot \ln\left(\frac{[Y]_{\text{out}}}{[Y]_{\text{in}}}\right) \right], \quad (1c)$$

for an antiporter. In the case of symporters, the flux J_{XY} is zero at $V = E_{XYs}$, with $E_{XYs} = \frac{n_X}{n_X z_X + n_Y z_Y} \cdot E_X + \frac{n_Y}{n_X z_X + n_Y z_Y} \cdot E_Y$. In the case of antiporters, it is zero at $V = E_{XYa}$, with $E_{XYa} = \frac{n_X}{n_X z_X - n_Y z_Y} \cdot E_X - \frac{n_Y}{n_X z_X - n_Y z_Y} \cdot E_Y$, if $n_X z_X - n_Y z_Y \neq 0$; otherwise it is zero if $n_X \cdot E_X = n_Y \cdot E_Y$.

As we will show now, this rudimentary information on $\Delta\mu = 0$ and $J = 0$ can be used to mathematically describe the flux in the steady state even without further knowledge of the function $J_X(V)$. The function $J_X(V)$ describes a curve in a 2-dimensional space (Figure 2a). We know from the above consideration that $J_X(E_X) = 0$ (Figure 2, blue point). This point is strategic because at E_X the direction of the flux changes, for example, if $J_X < 0$ at $V < E_X$, then $J_X > 0$ at $V > E_X$ (Figure 2, grey regions). In the steady state, both the membrane voltage and the flux through the transporter are constant. Thus, in this case, we need to describe just one point of the $J_X(V)$ curve (Figure 2b, red point). For such a description two coordinates are sufficient: One is the membrane voltage in steady state, V_{ss} , and the other is the flux in steady state, J_X^{ss} . Using triangulation, J_X^{ss} can be replaced by (Figure 2b, orange triangle)

$$J_X^{ss} = m \cdot (V_{ss} - E_X^{ss}), \quad (2)$$

with slope m of magnitude $m = \tan(\alpha)$. Flux values, $J_X(V)$ have the unit s^{-1} , while membrane voltage and E_X have the unit V. Therefore, the slope m has the unit $V^{-1} \cdot s^{-1}$. We can consider it as a free parameter (ranging from zero to infinity), which allows us

to reach any point on the vertical green line in [Figure 2b](#). In this way, any $J_X(V)$ curve is represented by E_X^{ss} , V_{ss} and the parameter m , even without knowing the exact shape of $J_X(V)$. m combines several physiologically important parameters because a change in the activity of the transporter protein is reflected by a change of the slope m (i.e. the angle α). An increase in activity, for instance by enhanced expression of the transporter or its activation by post-translational modifications, results in higher J -values ([Figure 2c](#), *dashed grey line*, purple point). This is reflected by a larger angle (α_1) and a larger slope (m_1). Conversely, a reduction in activity ([Figure 2c](#), *dotted grey line*, pink point) results in smaller J -values, a smaller angle (α_2) and a smaller slope (m_2). Thus, the parameter m gathers all regulatory features of the respective transporter. It can take on any value in the interval $[0, \infty)$. It should be noted, though, that m is generally not linear to biological parameters. The rather simple mathematical description of [equation \(2\)](#) therefore covers the entire range of possibilities without any constraints of approximations.

To illustrate this approach in practical terms, we develop it in the following, step by step, for (i) K^+ channels, (ii) H^+/K^+ symporters and (iii) H^+/K^+ antiporters. Finally, we will also introduce a suitable model for the (iv) H^+ -ATPase that primarily energises all transport processes.

(i) K^+ channels

The electrochemical gradient (compare [equation \(1a\)](#)) that determines the flux across K^+ channels is given in the case of highly selective K^+ channels by:

$$\Delta\mu_{K^+} = \mu_{K^+}^{\text{in}} - \mu_{K^+}^{\text{out}} = RT \cdot \ln \left(\frac{[K^+]_{\text{in}}}{[K^+]_{\text{out}}} \right) + F \cdot V, \quad (3)$$

with the internal and external K^+ concentrations $[K^+]_{\text{in}}$ and $[K^+]_{\text{out}}$, respectively. This gradient is zero at the zero-flux potential for K^+ channels, $V = E_K$, which is the Nernst potential for potassium

$$E_K = \frac{RT}{F} \cdot \ln \left(\frac{[K^+]_{\text{out}}}{[K^+]_{\text{in}}} \right). \quad (4)$$

Thus, at $V = E_K$ the function of the flux, $J_{K,KC}(V)$ (unit s^{-1}), has the value $J_{K,KC}(E_K) = 0$. Applying the same considerations that led to [equation \(2\)](#), the flux in steady state through the K^+ channel can be described by:

$$J_{K,KC}^{ss} = J_{K,KC}(V_{ss}) = m_{KC} \cdot (V_{ss} - E_K^{ss}). \quad (5)$$

The parameter m_{KC} (unit $V^{-1} \cdot s^{-1}$) determines the activity of the channels and comprises all potential regulatory features, such as functional protein expression, post-translational modifications and/or voltage dependence. However, it should be noted again that m_{KC} is in most cases not linear to these biological parameters. The net K^+ flux through the K^+ channels causes a transmembrane electric current (unit A) given by:

$$I_{KC} = e_0 \cdot J_{K,KC}, \quad (6)$$

with the elementary (positive) charge $e_0 (= 1.6 \times 10^{-19} \text{ A} \cdot \text{s})$.

(ii) H^+/K^+ symporters

The electrochemical gradient (compare [equation \(1b\)](#)) that determines the flux across a symporter with $n_s H^+/1 K^+$ stoichiometry is given by:

entry is given by:

$$\begin{aligned} \Delta\mu_{HKs} &= n_s \cdot (\mu_H^{\text{in}} - \mu_H^{\text{out}}) + (\mu_K^{\text{in}} - \mu_K^{\text{out}}) \\ &= RT \cdot \left[n_s \cdot \ln \left(\frac{[H^+]_{\text{in}}}{[H^+]_{\text{out}}} \right) + \ln \left(\frac{[K^+]_{\text{in}}}{[K^+]_{\text{out}}} \right) \right] + F \cdot (n_s + 1) \cdot V, \end{aligned} \quad (7)$$

with the internal and external proton concentrations $[H^+]_{\text{in}}$ and $[H^+]_{\text{out}}$, respectively. This gradient is zero at the zero-flux potential $V = E_{HKs}$ with

$$\begin{aligned} (n_s + 1) \cdot E_{HKs} \\ = \frac{RT}{F} \cdot \left[n_s \cdot \ln \left(\frac{[H^+]_{\text{out}}}{[H^+]_{\text{in}}} \right) + \ln \left(\frac{[K^+]_{\text{out}}}{[K^+]_{\text{in}}} \right) \right] = n_s \cdot E_H + E_K, \end{aligned} \quad (8)$$

and the Nernst potentials for potassium (E_K) and protons (E_H).

Hence, the net fluxes for K^+ and protons, respectively, at $V = E_{HKs}$ are $J_{K,HKs}(E_{HKs}) = 0$ and $J_{H,HKs}(E_{HKs}) = n_s \cdot J_{K,HKs}(E_{HKs}) = 0$. Applying the same considerations that led to [equation \(2\)](#), the fluxes in steady state can be described by:

$$J_{H,HKs}^{ss} = J_{H,HKs}(V_{ss}) = m_{HKs} \cdot n_s \cdot ((n_s + 1) \cdot V_{ss} - n_s \cdot E_H - E_K^{ss}), \quad (9)$$

$$J_{K,HKs}^{ss} = J_{K,HKs}(V_{ss}) = m_{HKs} \cdot ((n_s + 1) \cdot V_{ss} - n_s \cdot E_H - E_K^{ss}). \quad (10)$$

Also here, the parameter m_{HKs} gathers all regulatory features of the symporter. The transmembrane electric current (unit A) that is caused by the net H^+ and K^+ fluxes (unit s^{-1}) through the H^+/K^+ symporters is given by:

$$I_{HKs} = e_0 \cdot (J_{H,HKs} + J_{K,HKs}). \quad (11)$$

(iii) H^+/K^+ antiporters

The electrochemical gradient (compare [equation \(1c\)](#)) that determines the flux across an antiporter with $n_a H^+/1 K^+$ stoichiometry is given by:

$$\begin{aligned} \Delta\mu_{HKa} &= n_a \cdot (\mu_H^{\text{in}} - \mu_H^{\text{out}}) - (\mu_K^{\text{in}} - \mu_K^{\text{out}}) \\ &= RT \cdot \left[n_a \cdot \ln \left(\frac{[H^+]_{\text{in}}}{[H^+]_{\text{out}}} \right) - \ln \left(\frac{[K^+]_{\text{in}}}{[K^+]_{\text{out}}} \right) \right] + F \cdot (n_a - 1) \cdot V. \end{aligned} \quad (12)$$

This gradient is zero at E_{HKa} with

$$\begin{aligned} (n_a - 1) \cdot E_{HKa} \\ = \frac{RT}{F} \cdot \left[n_a \cdot \ln \left(\frac{[H^+]_{\text{out}}}{[H^+]_{\text{in}}} \right) - \ln \left(\frac{[K^+]_{\text{out}}}{[K^+]_{\text{in}}} \right) \right] = n_a \cdot E_H - E_K. \end{aligned} \quad (13)$$

If we apply again the same considerations that led to [equation \(2\)](#), the net fluxes for K^+ and H^+ in steady state can be expressed as:

$$J_{H,HKa}^{ss} = m_{HKa} \cdot n_a \cdot ((n_a - 1) \cdot V_{ss} - n_a \cdot E_H + E_K^{ss}). \quad (14)$$

$$J_{K,HKa}^{ss} = -m_{HKa} \cdot ((n_a - 1) \cdot V_{ss} - n_a \cdot E_H + E_K^{ss}). \quad (15)$$

Here as well, the parameter m_{HKa} combines all regulatory characteristics of the antiporter. The transmembrane electric current (unit A) that is caused by the net H^+ and K^+ fluxes (unit s^{-1}) through the H^+/K^+ antiporters is given by:

$$I_{HKa} = e_0 \cdot (J_{H,HKa} + J_{K,HKa}). \quad (16)$$

It is zero, if $n_a = 1$. In this case, the antiport would be electroneutral and the flux would not depend on the membrane voltage, but would only be proportional to the difference $E_H - E_K$ between the Nernst potentials of H^+ and K^+ .

(iv) H^+ -ATPase

Finally, we consider the proton pump as an active membrane transporter. The derivation of a mathematical description of the pump current of H^+ -ATPases was presented in detail in the [Supplementary Material](#) by Reyer et al. (2020). The mechanistic model of a pump cycle (Dreyer, 2017; Reyer et al., 2020) results in a sigmoidal curve for pump currents (unit A) that describes very well the experimental findings (Lohse & Hedrich, 1992):

$$I_{HATPase} = I_{Hmax} \cdot \frac{1 - e^{-\left(\frac{E}{RT} \cdot (V - V_{0,pump})\right)}}{1 + e^{-\left(\frac{E}{RT} \cdot (V+B)\right)} + e^{-\left(D \cdot \frac{E}{RT} \cdot (V+C)\right)}} = I_{Hmax} \cdot i_p(V), \quad (17)$$

with $i_p(V) = \frac{1 - e^{-\left(\frac{E}{RT} \cdot (V - V_{0,pump})\right)}}{1 + e^{-\left(\frac{E}{RT} \cdot (V+B)\right)} + e^{-\left(D \cdot \frac{E}{RT} \cdot (V+C)\right)}}$. The proton flux mediated by the H^+ -ATPase ($J_{HATPase}$; unit s^{-1}) can be determined by dividing the current by the elementary (positive) charge e_0 :

$$J_{HATPase} = \frac{I_{HATPase}}{e_0} = \frac{I_{Hmax}}{e_0} \cdot \frac{1 - e^{-\left(\frac{E}{RT} \cdot (V - V_{0,pump})\right)}}{1 + e^{-\left(\frac{E}{RT} \cdot (V+B)\right)} + e^{-\left(D \cdot \frac{E}{RT} \cdot (V+C)\right)}} = \frac{I_{Hmax}}{e_0} \cdot i_p(V). \quad (18)$$

Here, the numerical values of B, C and D are of minor importance for the shape of the curve. Suitable values are $B = 5.4$, $C = 2.5$, $D = 0.1$ (Dreyer, 2021a). Most important are the parameters I_{Hmax} and $V_{0,pump}$. I_{Hmax} determines the maximum pump current and is proportional to the number of active proton pumps in the membrane, while $V_{0,pump}$ is the voltage at which the pump current is zero [$i_p(V_{0,pump}) = 0$]. It depends in a complex manner on the cytosolic and apoplasmic proton concentrations and the cytosolic ATP, ADP and Pi concentrations (Rienmüller et al., 2012). For suitable simulations, in which the energy status of the cell does not change in the considered time interval, $V_{0,pump}$ can be set and kept constant (e.g. $V_{0,pump} = -200$ mV). This value determines the most negative value that the membrane voltage can attain.

2.2 Mathematical description of changes in concentrations and voltage

The proton and K^+ fluxes change the concentrations of H^+ and K^+ on both sides of the membrane. The combined net K^+ efflux ($J_K = J_{K,KC} + J_{K,KHs} + J_{K,KHa}$; unit s^{-1}) increases $[K^+]_{out}$ and decreases $[K^+]_{in}$, while the combined H^+ efflux ($J_H = J_{HATPase} + J_{H,KHs} + J_{H,KHa}$; unit s^{-1}) increases $[H^+]_{out}$ and decreases $[H^+]_{in}$. Additionally, the buffer capacities of the internal and external compartments can partially mitigate the changes in proton concentration, described by the general buffer reaction $H^+ + Buf^- \rightleftharpoons HBuf$ with an anionic base Buf^- and its conjugate acid, $HBuf$. All these changes are represented in mathematical terms by ordinary differential equations. The changes in K^+ concentrations are governed by:

$$\frac{d[K^+]_{in}}{dt} = \frac{-J_K}{Vol_{in} \cdot N_A} = \frac{-1}{Vol_{in} \cdot N_A} \cdot [J_{K,KC} + J_{K,KHs} + J_{K,KHa}]. \quad (19)$$

$$\frac{d[K^+]_{out}}{dt} = \frac{J_K}{Vol_{out} \cdot N_A} = \frac{1}{Vol_{out} \cdot N_A} \cdot [J_{K,KC} + J_{K,KHs} + J_{K,KHa}]. \quad (20)$$

Here N_A is the Avogadro constant and Vol_{in} and Vol_{out} are the volumes of the compartments on the respective side of the membrane. Changes in proton concentrations are determined by:

$$\frac{d[H^+]_{in}}{dt} = \frac{-1}{Vol_{in} \cdot N_A} \cdot \left\{ [J_{HATPase} + J_{H,KHs} + J_{H,KHa}] - k_{v,in} \cdot ([H^+]_{in} \cdot [Buf^-]_{in} - K_{s,in} \cdot [HBuf]_{in}) \right\}. \quad (21)$$

$$\frac{d[H^+]_{out}}{dt} = \frac{1}{Vol_{out} \cdot N_A} \cdot \left\{ [J_{HATPase} + J_{H,KHs} + J_{H,KHa}] - k_{v,out} \cdot ([H^+]_{out} \cdot [Buf^-]_{out} - K_{s,out} \cdot [HBuf]_{out}) \right\}. \quad (22)$$

Here, $K_{s,in} = 10^{-pK_{s,in}}$ and $K_{s,out} = 10^{-pK_{s,out}}$ indicate the dissociation constants of the buffer reactions that buffer pH_{in} and pH_{out} to $pK_{s,in}$ and $pK_{s,out}$, respectively. The buffer concentrations, in turn, change according to:

$$\begin{aligned} \frac{d[Buf^-]_{in}}{dt} &= -\frac{d[HBuf]_{in}}{dt} \\ &= \frac{-1}{Vol_{in} \cdot N_A} \cdot k_{v,in} \cdot ([H^+]_{in} \cdot [Buf^-]_{in} - K_{s,in} \cdot [HBuf]_{in}). \end{aligned} \quad (23)$$

$$\begin{aligned} \frac{d[Buf^-]_{out}}{dt} &= -\frac{d[HBuf]_{out}}{dt} \\ &= \frac{-1}{Vol_{out} \cdot N_A} \cdot k_{v,out} \cdot ([H^+]_{out} \cdot [Buf^-]_{out} - K_{s,out} \cdot [HBuf]_{out}). \end{aligned} \quad (24)$$

Compared to the transport reactions, the buffering reactions take place very quickly, which is reflected in large $k_{v,in}$ and $k_{v,out}$ values. Because of this difference in time scale, the parameters $k_{v,in}$ and $k_{v,out}$ do not need to be known in detail. In simulations, it is sufficient to set them 2–3 magnitudes larger than the other parameters (e.g. $k_{v,[in,out]}/(I_{max}/e_0) = 100 \mu M^{-2}$) to obtain almost instantaneous buffer reactions in comparison to the time-scale of transport.

The net fluxes usually cause a net charge transport across the membrane. This non-zero current provokes a change in the membrane voltage. The membrane is actually comparable to a dielectric in an electric capacitor that separates the charges in the aqueous interior from the aqueous exterior. Charge transport from one side to the other changes the membrane voltage according to:

$$\frac{dV}{dt} = \frac{-1}{C} \cdot [J_{HATPase} + I_{KC} + I_{HKs} + I_{HKa}], \quad (25)$$

with the membrane capacitance C (unit F).

2.3 Modelling the steady state with fixed transporters activities

At this point, we have translated [Figure 1](#) into the language of mathematics. For each transporter, we expressed the fluxes and currents in [equations \(5\), \(6\), \(9\)–\(11\)](#) and [\(14\)–\(18\)](#) with a few parameters. The dynamic properties of the system are determined by [equations \(19\)–\(25\)](#). In the following, we will solve the differential equations for homeostatic conditions. If the system is considered in a steady state, neither the membrane voltage nor the concentrations change

with time, which means that the left sides of equations (19)–(25) are zero. In this condition, the equations (19)–(25) simplify to two non-redundant equations taking also into account that $I_X = e_0 \cdot J_X$:

$$0 = J_{K,KC}^{ss} + J_{K,HKS}^{ss} + J_{K,HKa}^{ss}. \quad (26)$$

$$0 = J_{HATPase}^{ss} + J_{H,HKS}^{ss} + J_{H,HKa}^{ss}. \quad (27)$$

All the other equations are either zero or linear combinations of the equations (26) and (27). In the next step, the J_X^{ss} were replaced by the expressions deduced in equations (5), (9), (10), (14), (15) and (18) yielding:

$$0 = m_{KC} \cdot (V_{ss} - E_K^{ss}) + m_{HKS} \cdot ((n_s + 1) \cdot V_{ss} - n_s \cdot E_H - E_K^{ss}) - m_{HKa} \cdot ((n_a - 1) \cdot V_{ss} - n_a \cdot E_H + E_K^{ss}). \quad (28)$$

$$0 = \frac{I_{Hmax}}{e_0} \cdot i_p(V_{ss}) + n_s \cdot m_{HKS} \cdot ((n_s + 1) \cdot V_{ss} - n_s \cdot E_H - E_K^{ss}) + n_a \cdot m_{HKa} \cdot ((n_a - 1) \cdot V_{ss} - n_a \cdot E_H + E_K^{ss}). \quad (29)$$

Although the mathematical parameters m_X can depend on relevant biological parameters such as the K^+ and H^+ concentrations or V (in a linear and non-linear way), they are constant in the steady state and are therefore fixed numbers with units. Then, we multiplied both equations with the factor e_0/I_{Hmax} and define $g_X := m_X \cdot e_0/I_{Hmax}$ (unit V^{-1}). This operation eliminated a redundant parameter and reduced the set of four parameters (I_{Hmax} , m_{KC} , m_{HKS} , m_{HKa}) to a set of three (g_{KC} , g_{HKS} , g_{HKa}) representing the relative activity of the transporter proteins (relative to the maximal activity of the H^+ -ATPase).

$$0 = g_{KC} \cdot (V_{ss} - E_K^{ss}) + g_{HKS} \cdot ((n_s + 1) \cdot V_{ss} - n_s \cdot E_H - E_K^{ss}) - g_{HKa} \cdot ((n_a - 1) \cdot V_{ss} - n_a \cdot E_H + E_K^{ss}). \quad (30)$$

$$0 = i_p(V_{ss}) + n_s \cdot g_{HKS} \cdot ((n_s + 1) \cdot V_{ss} - n_s \cdot E_H - E_K^{ss}) + n_a \cdot g_{HKa} \cdot ((n_a - 1) \cdot V_{ss} - n_a \cdot E_H + E_K^{ss}). \quad (31)$$

Additionally, the equations (30) and (31) could be arranged in vector and matrix form:

$$M \bullet \begin{pmatrix} V_{ss} \\ E_K^{ss} \end{pmatrix} = \vec{A}, \quad (32)$$

with:

$$M = \begin{pmatrix} g_{KC} + (n_s + 1) \cdot g_{HKS} - (n_a - 1) \cdot g_{HKa} & -g_{KC} - g_{HKS} - g_{HKa} \\ n_s \cdot (n_s + 1) \cdot g_{HKS} + n_a \cdot (n_a - 1) \cdot g_{HKa} & -n_s \cdot g_{HKS} + n_a \cdot g_{HKa} \end{pmatrix}, \quad (33)$$

and:

$$\vec{A} = \begin{pmatrix} n_s \cdot g_{HKS} \cdot E_H - n_a \cdot g_{HKa} \cdot E_H \\ n_s^2 \cdot g_{HKS} \cdot E_H + n_a^2 \cdot g_{HKa} \cdot E_H - i_p(V_{ss}) \end{pmatrix}. \quad (34)$$

This might be considered as just a formalism and not needed for two equations. However, the conversion should illustrate that we have opened the powerful toolbox of linear algebra. More complex homeostats with more than two equations can be handled in the same way and the tools from linear algebra for solving this type of equation can be applied in the same manner. Equation (32) has exactly one solution for the $(V_{ss}|E_K^{ss})$ pair that depends on the

activities of the transporter proteins (g_X) and the proton gradient (E_H):

$$V_{ss} - E_H + i_p(V_{ss}) \cdot \frac{g_{KC} + g_{HKS} + g_{HKa}}{(n_s + n_a)^2 \cdot g_{HKS} \cdot g_{HKa} + g_{KC} \cdot (n_s^2 \cdot g_{HKS} + n_a^2 \cdot g_{HKa})} = 0. \quad (35)$$

$$E_K^{ss} = E_H - i_p(V_{ss}) \cdot \frac{g_{KC} + (n_s + 1) \cdot g_{HKS} - (n_a - 1) \cdot g_{HKa}}{(n_s + n_a)^2 \cdot g_{HKS} \cdot g_{HKa} + g_{KC} \cdot (n_s^2 \cdot g_{HKS} + n_a^2 \cdot g_{HKa})} \quad (36)$$

$$= V_{ss} - i_p(V_{ss}) \cdot \frac{n_s \cdot g_{HKS} - n_a \cdot g_{HKa}}{(n_s + n_a)^2 \cdot g_{HKS} \cdot g_{HKa} + g_{KC} \cdot (n_s^2 \cdot g_{HKS} + n_a^2 \cdot g_{HKa})}.$$

Please note

- (1) Equations (35) and (36) are not defined for cases in which two of the three parameters g_{KC} , g_{HKS} and g_{HKa} are zero. In cases, in which only one g_X is different from zero, the equations (30) and (31) result in:

$$\begin{aligned} g_{KC} = g_{HKS} = 0 \text{ (only active } H^+/K^+ \text{ antiporters): } & V_{ss} = V_{0,pump}, E_K^{ss} = n_a \cdot E_H - (n_a - 1) \cdot V_{0,pump} \\ g_{KC} = g_{HKa} = 0 \text{ (only active } H^+/K^+ \text{ symporters): } & V_{ss} = V_{0,pump}, E_K^{ss} = (n_s + 1) \cdot V_{0,pump} - n_s \cdot E_H \\ g_{HKS} = g_{HKa} = 0 \text{ (only active } K^+ \text{ channels): } & V_{ss} = V_{0,pump}, E_K^{ss} = V_{0,pump} \end{aligned}$$

- (2) Equation (35); of type $V_{ss} - A + i_p(V_{ss}) \cdot B = 0$, is an implicit solution. It cannot be explicitly solved analytically for V_{ss} because $i_p(V_{ss})$ is a function of V_{ss} . Nevertheless, mathematical tools also allow us to bypass this difficulty. The left-hand side of equation (35) before the equals sign is a strictly monotonically increasing function of V_{ss} , which means that the first derivative after V_{ss} is > 0 . Or in other words, with increasing V_{ss} , the left-hand side of the equation also increases, starting from negative values at negative V_{ss} and reaching positive values at positive V_{ss} . The corresponding curve therefore cuts the zero axis only once. Thus, for given values of $A = E_H$ and $B = f(g_{KC}, g_{HKS}, g_{HKa})$ there is exactly one V_{ss} that obeys this equation. The system is free from potential bifurcation. If E_H , g_{KC} , g_{HKS} and g_{HKa} are known, the value of V_{ss} can be determined numerically by root-finding algorithms, such as the Newton–Raphson method.

3. Results

The presented thermodynamical and mathematical analysis of the transporter network has resulted in general solutions for V_{ss} (equation (35)) and E_K^{ss} (equation (36)) in the steady state, that is, in homeostatic conditions. These values could be influenced by the cell via the proton gradient E_H and the parameters g_{KC} , g_{HKS} and g_{HKa} , that is, the (relative) activities of the different K^+ transporters. Considering the fact that from a physiological point of view, the proton gradient is less flexible, the main setscrews to adjust $(V_{ss}|E_K^{ss})$ are the g_X values. These three mathematical parameters split in the biological reality into a manifold of physiological parameters, such as gene expression, protein turnover and post-translational regulation. Thus, one g_X value can represent several different biological realities.

To illustrate the consequences of the dependency of the homeostatic steady state on the parameters g_{KC} , g_{HKs} and g_{HKa} , the results for the case $n_s = 1$, $n_a = 1$, $V_{0,pump} = -200$ mV, and $E_H = +57.6$ mV ($pH_{in} = 7$, $pH_{out} = 6$) are shown as an example. Below, we will show how different settings of these parameters influence the results. For each parameter g_X , we chose 0 and 19 logarithmically distributed values in a range between 10^{-6} mV $^{-1}$ and 1 mV $^{-1}$ (i.e. 0 mV $^{-1}$, 1×10^{-6} mV $^{-1}$, 2×10^{-6} mV $^{-1}$, 5×10^{-6} mV $^{-1}$, 1×10^{-5} mV $^{-1}$, 2×10^{-5} mV $^{-1}$, 5×10^{-5} mV $^{-1}$, 1×10^{-4} mV $^{-1}$, 2×10^{-4} mV $^{-1}$, 5×10^{-4} mV $^{-1}$, 1×10^{-3} mV $^{-1}$, 2×10^{-3} mV $^{-1}$, 5×10^{-3} mV $^{-1}$, 1×10^{-2} mV $^{-1}$, 2×10^{-2} mV $^{-1}$, 5×10^{-2} mV $^{-1}$, 1×10^{-1} mV $^{-1}$, 2×10^{-1} mV $^{-1}$, 5×10^{-1} mV $^{-1}$, 1 mV $^{-1}$). With respect to Figure 2b, this range covered a spectrum of the angle α between 0° and almost 90° and thus the entire range of possibilities. The resulting $20 \times 20 \times 20$ table represented 8000 different (mathematical) realities of the system. For each of them, equation (35) was solved using the 'Goal Seek' routine in Excel by changing V_{ss} . This was done to show that no sophisticated computer programs are required for the analyses. With the resulting value for V_{ss} , then the value for E_K^{ss} was calculated using equation (36). The determined ($V_{ss}|E_K^{ss}$) pair finally allowed us to calculate the different relative fluxes in steady state using equations (5), (9), (10), (14), (15) and (18) and the definition $g_X := m_X \cdot e_0 / I_{Hmax}$ (see above):

$$J_{K,KC}^{ss,rel} = g_{KC} \cdot (V_{ss} - E_K^{ss}), \quad (37)$$

$$J_{H,HKs}^{ss,rel} = g_{HKs} \cdot (2 \cdot V_{ss} - E_H - E_K^{ss}), \quad (38)$$

$$J_{K,HKs}^{ss,rel} = g_{HKs} \cdot (2 \cdot V_{ss} - E_H - E_K^{ss}), \quad (39)$$

$$J_{H,HKa}^{ss,rel} = g_{HKa} \cdot (E_K^{ss} - E_H), \quad (40)$$

$$J_{K,HKa}^{ss,rel} = -g_{HKa} \cdot (E_K^{ss} - E_H), \quad (41)$$

$$J_{HATPase}^{ss,rel} = i_p(V_{ss}) = \frac{1 - e^{-\left(\frac{F}{RT}\right) \cdot (V_{ss} - V_{0,pump})}}{1 + e^{-\left(\frac{F}{RT}\right) \cdot V_{ss} + 5.4} + e^{-\left(0.1 \cdot \frac{F}{RT}\right) \cdot V_{ss} + 2.5}}. \quad (42)$$

3.1 K^+ and H^+ cycling in steady state

In the 8000 different cases, V_{ss} ranged between -200 mV ($= V_{0,pump}$) and $+57.6$ mV ($= E_H$), while E_K^{ss} assumed values between -457.6 mV ($= 2 \cdot V_{0,pump} - E_H$) and $+57.6$ mV ($= E_H$). Figure 3 illustrates the values of V_{ss} (a,d,g), E_K^{ss} (b,e,h) and $E_K^{ss} - V_{ss}$ (c,f,i) for several parameter sets of g_{KC} , g_{HKs} and g_{HKa} . The larger was the activity of the K^+ channel ($b < e < h$), the less negative was the minimal E_K^{ss} that could be achieved by highly active H^+/K^+ symporters. With hardly any active K^+ channels ($g_{KC} = 10^{-5}$ V $^{-1}$) the symporter could (theoretically) accumulate a $[K^+]_{in}$ that was almost 10^8 -fold higher than $[K^+]_{out}$, which corresponded to $E_K^{ss} \approx -460$ mV (Figure 3b). In this condition, the membrane voltage was $V_{ss} \approx -200$ mV (Figure 3a), that is, close to the limit of the pump $V_{0,pump}$. This means that all energy from the proton gradient and ATP-hydrolysis was used for K^+ accumulation. These extreme values became more moderate with increasing channel activity. At 500-fold higher K^+ channel activity ($g_{KC} = 5 \times 10^{-3}$ V $^{-1}$), $E_K^{ss} = -244$ mV was the most negative value at high g_{HKs} and low g_{HKa} (Figure 3e), which still corresponded to $\sim 17,000$ -fold higher $[K^+]_{in}$ than $[K^+]_{out}$. The reduction in the accumulation rate came along with an increased V_{ss} , in particular at higher symporter but also at higher antiporter activities (Figure 3d) pointing to an energy-dissipation process that increased with increasing K^+ channel activity (Figure 3a,d,g).

This was further corroborated when analysing the transmembrane fluxes (Supplementary Figure S1). Although the net fluxes of K^+ and H^+ were zero in steady state (equations (26) and (27)), there was a transmembrane cycling of both ions. Permanent effluxes were compensated by permanent influxes. To illustrate the cycling, the H^+ and K^+ cycling flux amplitudes and the ratio between the two were displayed in Figure 4 relative to the maximally achievable proton pump-driven H^+ efflux; that is, the maximum H^+ efflux of the pump (I_{Hmax}/e_0 , equation (18)) was normalised to 1. If the K^+ channel activity was very low ($g_{KC} = 10^{-5}$ V $^{-1}$), the relative H^+ efflux mediated by the pump ranged from 0 to ≈ 0.94 [$= i_p(E_H)$] with the highest value achieved with highly active sym- and antiporters (Figure 4a and Supplementary Figure S1A) at $V_{ss} = E_H$ (Figure 3a). Under these conditions, the relative K^+ cycling flux was half as large as the H^+ flux (Figure 4b), indicating that two protons were looped for one K^+ ion (Figure 4c). And indeed, one H^+ was taken up together with one K^+ by the H^+/K^+ symporter (Supplementary Figure S1B,E), while the other H^+ was taken up by the H^+/K^+ antiporter releasing one K^+ (Supplementary Figure S1C,F). The accumulated protons were released by the pump (Supplementary Figure S1A).

H^+ and K^+ cycling flux amplitudes became smaller with either decreasing symporter or decreasing antiporter activity (Figure 4a,b). This picture changed with increasing K^+ channel activity. While the relative H^+ and K^+ fluxes remained unaffected by an increased channel activity at very high sym- and antiporter activity (compare the plateaus in the corners of Figure 4a,b,d,e,g,h), K^+ channel activity had a strong effect when one of the H^+/K^+ transporters was less active. With less active antiporters and highly active symporters, increased K^+ channel activity increased K^+ cycling (compare Figure 4b,e,h, close to the magenta curve). The K^+ efflux was mediated by the K^+ channels (Supplementary Figure S1D,J,P), compensated by a larger K^+ influx via the H^+/K^+ symporters (Supplementary Figure S1E,K,Q). The accompanying H^+ influx (Supplementary Figure S1B,H,N) was neutralised by the H^+ efflux via the pump (Supplementary Figure S1A,G,M) that also energised the combined H^+/K^+ cycling.

Likewise, K^+ cycling also increased with increased K^+ channel activity at highly active antiporters and less active symporters (compare Figure 4b,e,h, close to the cyan curve). However, this time, the efflux was not mediated by the K^+ channels (Supplementary Figure S1D,J,P). They mediated K^+ influx instead. The K^+ efflux passed through the H^+/K^+ antiporters (Supplementary Figure S1F,L,R). When comparing the two situations, it turned out that in homeostatic steady state conditions, K^+ channels served at the same membrane voltage, V_{ss} , once as uptake and once as release channels depending on the H^+/K^+ transporter situation. In combination with H^+/K^+ symporters, they acted as K^+ release channels, even at very negative voltages. In contrast, in combination with H^+/K^+ antiporters, they functioned as K^+ uptake channels, even at positive voltages. These thermodynamically derived properties of K^+ channels under homeostatic conditions apparently contradict the historically established separation of voltage-dependent K^+ channels into hyperpolarisation-activated uptake (K_{in}) and depolarization-activated release (K_{out}) channels (Dreyer et al., 2021; Dreyer & Blatt, 2009; Dreyer & Uozumi, 2011; Sharma et al., 2013). Thermodynamic considerations have now taught us that the nomenclature might be misleading. K_{in} channels might also serve as K^+ release channels to avoid over-accumulation of K^+ by H^+/K^+ symporters, while K_{out} channels may also serve as K^+ uptake channels under certain homeostatic conditions.

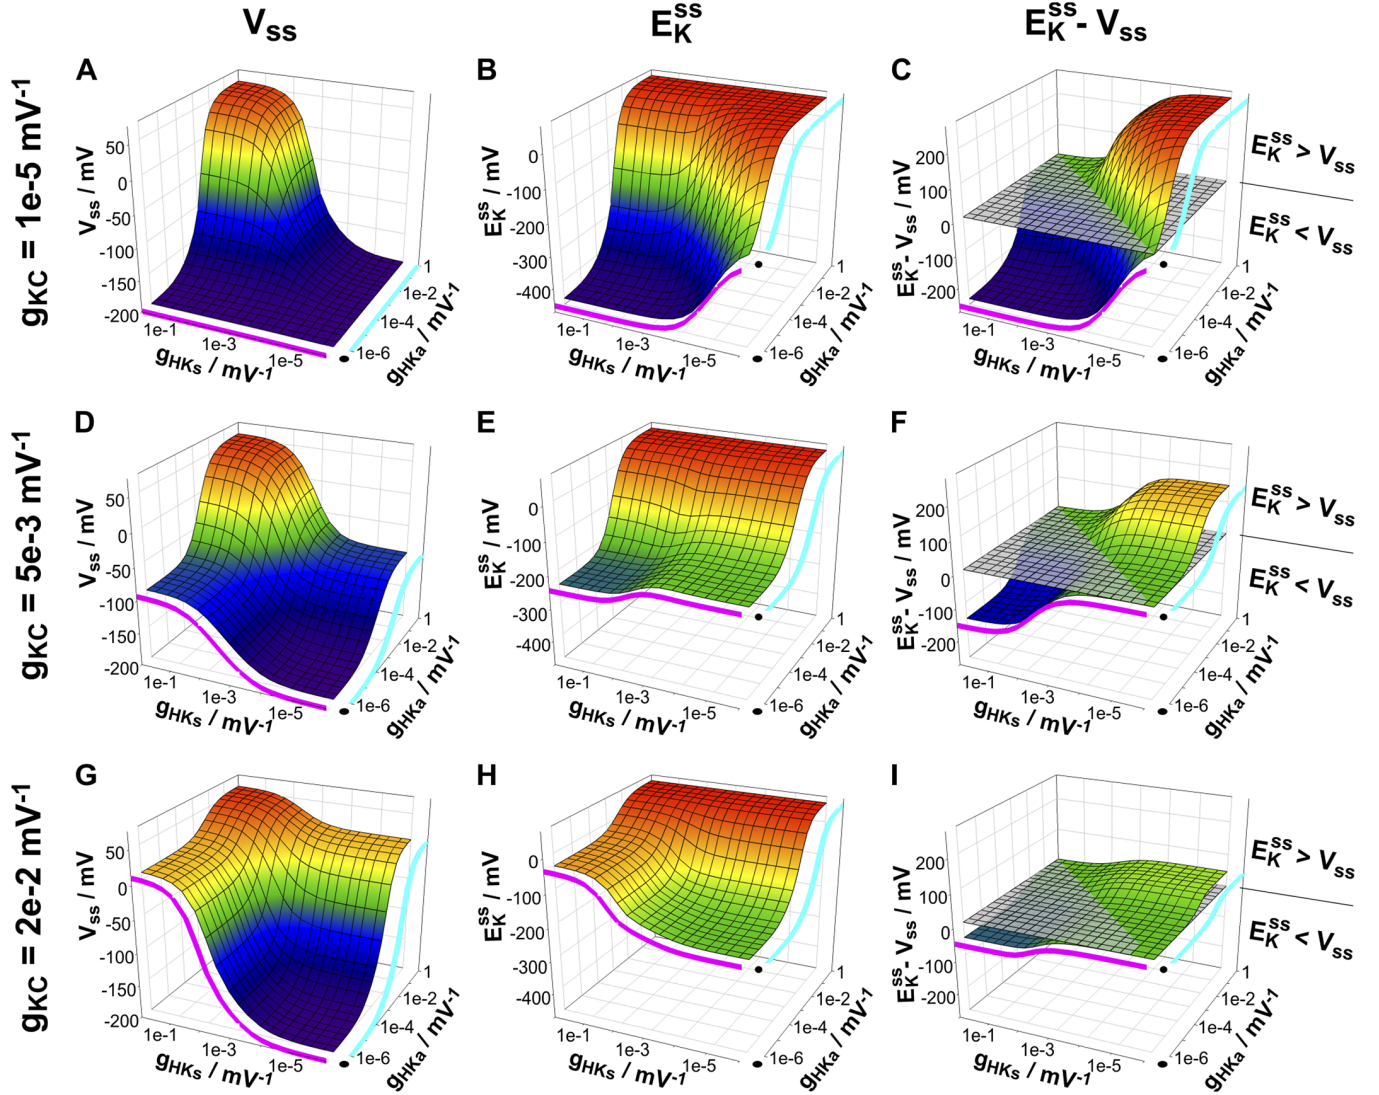

Figure 3. Membrane voltage and K^+ gradient in homeostatic (steady state) conditions. The activities of K^+ channels (g_{KC}), H^+/K^+ symporters (g_{HKs}) and H^+/K^+ antiporters (g_{HKa}) determine the membrane voltage (V_{ss} , a,d,g) and the K^+ gradient (E_K^{ss} , b,e,h) in steady state. The difference $E_K^{ss} - V_{ss}$ (c,f,i) is positive if the activity of antiporters is higher than that of symporters ($g_{HKa} > g_{HKs}$). It is negative if $g_{HKa} < g_{HKs}$. Data were calculated for the case $n_s = 1$, $n_o = 1$, $V_{0,pump} = -200$ mV, and $E_H = +57.6$ mV ($\Delta pH = 1$). The magenta lines show the values in the absence of active H^+/K^+ antiporters ($g_{HKa} = 0$), whereas the cyan lines indicate the values in the absence of active H^+/K^+ symporters ($g_{HKs} = 0$).

3.2 Conclusions on the cost efficiency of homeostasis

The considerations based on thermodynamic first principles indicated that homeostatic conditions can be achieved by combining two different K^+ transporter types (K^+ channels and H^+/K^+ symporters, Figure 5a, K^+ channels and H^+/K^+ antiporters, Figure 5b, H^+/K^+ symporters and H^+/K^+ antiporters, Figure 5c) or all three K^+ transporter types (Figure 5d). In all these cases, the homeostatic condition is inevitably accompanied by energy-consuming H^+ and K^+ loops across the membrane (Dreyer, 2021a). In Figures 3 and 4 and Supplementary Figure S1 this was shown exemplarily for sym- and antiporters with a 1 H^+ :1 K^+ stoichiometry. In the following, the more general case (n_s and n_a) was considered to find out which values for n_s and n_a make the most sense. The H^+ and K^+ cycles occurred because the homeostatic steady state was different from the equilibrium states of the different involved transporters. In the case of a transporter network with H^+ pump, K^+ channel and H^+/K^+ symporter (Figure 5a), for instance, the steady state

membrane voltage, V_{ss} , is different from the equilibrium voltages of the pump ($V_{0,pump}$), the channel (E_K^{ss}) or the symporter ($E_{HKs} = [n_s \cdot E_H + E_K^{ss}] / [n_s + 1]$). This means that the pump continuously pumps protons from the inside to the outside by consuming ATP. These protons return to the cell via the H^+/K^+ symporter and shuttle 1 K^+ per n_s protons into the cell. The absorbed K^+ is released again via the channel. These combined H^+ and K^+ cycles are yield-neutral in steady state, that is, they do not affect neither the concentrations nor the electrical charges at both sides of the membrane. The cost of the homeostatic condition for the cell is in this case n_s ATP per 1 looped K^+ . Most cost-efficient would therefore be $n_s = 1$. And indeed, even at this lowest coupling rate, the H^+/K^+ symporter is powerful enough to (theoretically) accumulate K^+ under physiological voltage ($V \geq -200$ mV) and pH ($\Delta pH = 1$) conditions more than 10^5 -fold in the interior compared to the exterior ($E_K^{ss} = -287.8$ mV). Higher coupling rates ($n_s > 1$) would allow higher accumulation rates, but at the expense of higher ATP consumption. Considering the physiological conditions, the best

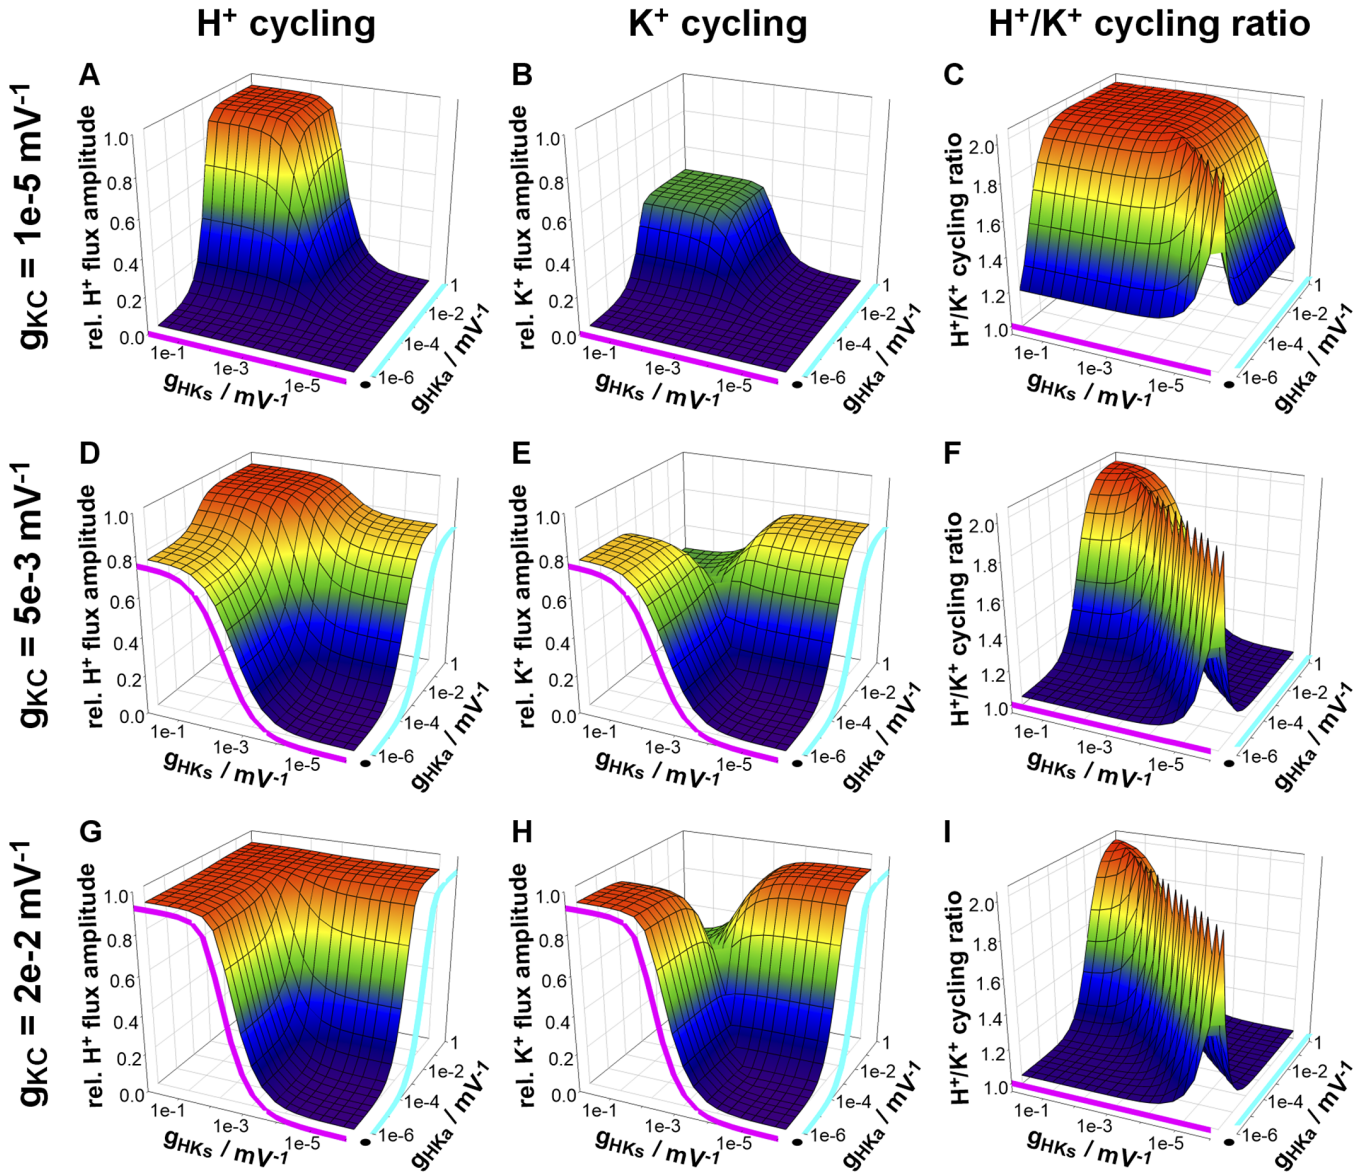

Figure 4. H^+ and K^+ cycling in homeostatic (steady state) conditions. Although the net H^+ and K^+ fluxes are zero in homeostatic conditions, there are still continuous H^+ and K^+ effluxes that are compensated by influxes of the same magnitude. (a,d,g) Dependency of the H^+ flux amplitude and (b,e,h) of the K^+ flux amplitude on the activities of the K^+ channels (g_{KC}), H^+ / K^+ symporters (g_{HKs}) and H^+ / K^+ antiporters (g_{HKa}). The cycling fluxes are shown relative to the maximal H^+ efflux that can be generated by the H^+ ATPase ($J_{Hmax} = I_{Hmax}/e_0$). (c,f,i) Ratio between H^+ and K^+ cycling fluxes as a measure for the H^+ / K^+ cycling ratio. Data were calculated for the case $n_s = 1$, $n_a = 1$, $V_{0,pump} = -200$ mV and $E_H = +57.6$ mV ($\Delta pH = 1$). The magenta lines show the values in the absence of active H^+ / K^+ antiporters ($g_{HKa} = 0$), whereas the cyan lines indicate the values in the absence of active H^+ / K^+ symporters ($g_{HKs} = 0$).

cost-benefit ratio is therefore $n_s = 1$. The K^+ transporter network shown in Figure 5a is very well suited for K^+ accumulation, in particular when $[K^+]_{out}$ is small. However, it has the potential problem of K^+ overaccumulation under certain conditions (moderate $[K^+]_{out}$). The grey area in Figure 5a (lower panel) indicates the reachable range for V_{ss} and E_K^{ss} . This transporter network only allows steady state conditions with $E_K^{ss} \leq V_{ss}$, which might imply rather high $[K^+]_{in}$. This drawback could be eliminated by replacing the H^+ / K^+ symporter with an H^+ / K^+ antiporter (Figure 5b). The network of pump, channel and antiporter can establish homeostatic conditions with $V_{ss} \leq E_K^{ss}$, and might therefore be suitable for moderate $[K^+]_{out}$. In a steady state, the protons pumped out of the cell are reaccumulated by the antiporter, which releases K^+ , that is then reabsorbed by the channel. The cost of these H^+ and K^+ cycles is n_a

ATP per 1 looped K^+ . The n_a value only affects the upper limit of E_K^{ss} . For $n_a = 1$, E_K^{ss} cannot be larger than E_H (Figure 5b, lower panel, grey area). Higher n_a values would allow $E_K^{ss} > E_H$. However, this is physiologically not relevant because it would mean very low $[K^+]_{in}$. Thus, H^+ / K^+ antiporters with $n_a = 1$ are the most cost-efficient, that is, they function as electroneutral transporters. The limits of the two formerly considered networks can be overcome by combining the H^+ pump with H^+ / K^+ sym- and antiporters (Figure 5c). Here, the combined range of ($V_{ss}|E_K^{ss}$) pairs is in reach (light and dark grey areas). The drawback is, however, the increased cost of ($n_s + n_a$) ATP per 1 looped K^+ , that is, 2 ATP per 1 cycled K^+ in the most cost-efficient case. The cost can be reduced by including additionally K^+ channels into the transporter network (Figure 5d). Without any compromise on the range of the reachable ($V_{ss}|E_K^{ss}$) pairs, 1 looped

Figure 5. K homeostats in a steady state. The three different K⁺ transporter types (i) K⁺ channels (KC), (ii) H⁺/K⁺ symporters (H/Ks, stoichiometry n_s H⁺ : 1 K⁺) and (iii) H⁺/K⁺ antiporters (H/Ka, stoichiometry n_a H⁺ : 1 K⁺) can be arranged to a K homeostat in four different combinations. In all combinations the transmembrane, yield-neutral, but energy-consuming cycling of H⁺ and K⁺ is a feature of the steady state condition. (a) A network of H⁺-pumps, K⁺ channels and H⁺/K⁺ symporters consumes n_s ATP per 1 looped K⁺, but allows only conditions for which $E_K^{ss} \leq V_{ss}$ (dark grey area, shown for the most cost-efficient case $n_s = 1$). (b) A network of H⁺-pumps, K⁺ channels and H⁺/K⁺ antiporters consumes n_a ATP per 1 looped K⁺, but allows only conditions for which $E_K^{ss} \geq V_{ss}$ (light grey area, shown for the most cost-efficient case $n_a = 1$). (c) A network of H⁺-pumps, H⁺/K⁺ symporters and H⁺/K⁺ antiporters consumes (n_s+n_a) ATP per 1 looped K⁺. It allows a broader range of $(V_{ss}|E_K^{ss})$ pairs (combined grey areas, shown for the most cost-efficient case $n_s = n_a = 1$). (d) A network of H⁺-pumps, K⁺ channels, H⁺/K⁺ symporters and H⁺/K⁺ antiporters allows the same broad range of $(V_{ss}|E_K^{ss})$ pairs as in (c) (combined grey areas, shown for the most cost-efficient case $n_s = n_a = 1$). However, the ATP consumption is smaller and ranges between 1 and 2 ATP per 1 looped K⁺ (in the most cost-efficient case $n_s = n_a = 1$). The dotted blue and red lines in the lower panels indicate roughly physiological upper and lower limits for E_K^{ss} at an endomembrane and the plasma membrane: +20 mV refers to $[K^+]_{out}/[K^+]_{in} \approx 2.3$ (e.g. 267mM/120mM), -50 mV refers to $[K^+]_{out}/[K^+]_{in} \approx 0.13$ (e.g. 16 mM/120 mM), while -250 mV refers to $[K^+]_{out}/[K^+]_{in} \approx 4.5 \times 10^{-5}$ (5 μ M/120 mM) (adapted from Dreyer, 2021a).

K⁺ costs here 1–2 ATP (in the most cost-efficient case $n_s = n_a = 1$, Figure 4c,f,i).

3.3 Independence of the conclusions on the parameters $V_{0,pump}$ and E_H

The previous results were obtained for a fixed zero current voltage of the pump ($V_{0,pump} = -200$ mV) and a fixed pH gradient of $\Delta pH = 1$ ($E_H = 57.6$ mV). To corroborate that different settings do not change the main conclusions, we have repeated the analysis with $V_{0,pump} = -150$ mV and $E_H = 126.6$ mV ($pH_{in} = 7.2$, $pH_{out} = 5.0$) as two examples (Supplementary Figure S2). The different $V_{0,pump}$ and E_H values mainly affected the extreme values of V_{ss} and E_K^{ss} , but left the main trends unaffected. Likewise, the H⁺ and K⁺ cycling fluxes were barely distinguishable between $V_{0,pump} = -200$ mV (Supplementary Figure S1) and $V_{0,pump} = -150$ mV (Supplementary Figure S3). A less negative $V_{0,pump}$ may represent energy consumption by other transport processes, for example, by an anion homeostat. The cycling fluxes in steady state are independent of E_H : If V_{ss} and E_K^{ss} are replaced by the solutions of equations (35) and (36) in equations (37)–(42), all J_X^{ss} do not depend on E_H or a buffer concentration. This supports the notion that a buffer, which can only be available in a limited concentration, does not contribute to the maintenance of homeostasis.

4. Discussion and conclusion

Cellular ion homeostasis is governed by fundamental physical and chemical laws. In this study, we used (i) the definition of the electrochemical potential, (ii) the basic consequence from this

definition that net fluxes are zero if there is no gradient in the electrochemical potential, (iii) the chemical definition of concentrations and concentration changes, (iv) the physical properties of membranes to separate charges like a technical capacitor and we (v) assumed that the considered transporters function as perfect molecular machines as shown exemplarily for several of them (e.g. Carpaneto et al., 2005). We described the different processes with mathematical equations and took advantage of the powerful toolboxes of differential equations and linear algebra. These basic considerations were sufficient to draw fundamental conclusions about the behaviour of K⁺ transporter networks responsible for setting homeostatic (steady state) conditions for potassium in a cellular or organelle environment:

- (1) By setting the transporter activities (g_X), the cell can precisely adjust the steady state values for the membrane voltage V_{ss} and the transmembrane K⁺ gradient E_K^{ss} . A cell can change the parameters g_X by altering the activities through gene expression and post-translational modifications (e.g. phosphorylation), which points to the adjusting screws that integrate the homeostats into the cellular regulatory networks. It should be emphasised, however, that the g_X values usually do not follow the biological parameters in a linear manner.
- (2) The cell cannot adjust $[K^+]_{in}$ independent of $[K^+]_{out}$; it can only adjust E_K^{ss} , which depends on both.
- (3) If the membrane has only one functional K⁺ transporter type, that is, all g_X except one are zero, the steady state is independent of the activity of this transporter and cannot

- be adjusted. In other words: Homeostatic conditions involve always at least two different types of transporters.
- (4) Transporter types are only different, if they are energised differently, that is, the driving gradient $\Delta\mu$ is different. For instance, voltage-dependent and voltage-independent K^+ channels are not different; both are described by the same type of equations. The voltage dependence is covered by the g_{KC} parameters, and several g_{KC} values could be combined to one that represents all channels.
 - (5) A steady state condition of $E_K^{ss} < V_{ss}$, is (indirect) proof of functional H^+/K^+ symporters in the membrane. The condition $E_K^{ss} < V_{ss}$ is only achievable with $g_{HKs} > 0$.
 - (6) Most cost-efficient are symporters of 1 H^+ : 1 K^+ stoichiometry.
 - (7) A steady state condition of $V_{ss} < E_K^{ss}$ is (indirect) proof of functional H^+/K^+ antiporters in the membrane. The condition $V_{ss} < E_K^{ss}$ is only achievable with $g_{HKa} > 0$.
 - (8) Most cost-efficient are antiporters of 1 H^+ : 1 K^+ stoichiometry, that is, they function as electroneutral antiporters.
 - (9) Hyperpolarisation-activated K_{in} channels may serve in homeostatic conditions as K^+ release channels when acting together with H^+/K^+ symporters.
 - (10) Depolarization-activated K_{out} channels may serve in homeostatic conditions as K^+ uptake channels when acting together with H^+/K^+ antiporters.

It might be surprising that all these far-reaching conclusions could be drawn solely from the knowledge on the thermodynamics of the different transport processes ($\Delta\mu$). More knowledge about the transporters (e.g. K_M -values or voltage-dependence) was *not* necessary. Actually, all these details are covered by the g_x values. In this study, we set the g_x values, without considering how they are set and determined the resulting steady state. This approach must be seen separate from the adjustments in a real cell. There, the setting of the g_x values is the consequence of complex cellular processes that also involve feedback loops, such as the regulation of g_x by membrane voltage. Nevertheless, once the homeostatic steady state has been established, the g_x are also stable. This is actually the starting point of the thought experiments presented here.

The finding that the basic principle of homeostasis (steady state) does not depend on molecular details but shows a universal pattern that can be achieved in a huge variety of different nuances, indicates the enormous robustness of the biological system. It is therefore highly tolerant towards disturbances, such as many mutations in the transporter proteins and could be maintained even in dramatic evolutionary processes. It is thus not individual transporters but rather transporter networks (homeostats) that govern membrane transport and associated homeostatic processes in plant cells.

Conclusions (5–8) are of particular interest. The modelling of the K homeostat points to the existence of both, H^+/K^+ symporters and H^+/K^+ antiporters. (a) $E_K^{ss} < V_{ss}$ at steady state implies the participation of active H^+/K^+ symporters in the homeostat, while (b) $V_{ss} < E_K^{ss}$ indicates the presence of active H^+/K^+ antiporters. A condition of $V < E_K$ is not a temporary exception, but is observed quite frequently in plant cells (Koers et al., 2011; Roelfsema et al., 2001, 2002; Thiel et al., 1992). It might be that these cells were not in a steady state but in an ongoing process of K^+ accumulation. However, without H^+/K^+ antiporters, the steady state would always be $E_K^{ss} \leq V_{ss}$, which could lead to rather large K^+ gradients, especially

if the external K^+ concentration is in the mM range, as is often the case in tissues outside the roots. In such conditions, H^+/K^+ antiporters would serve as security valves against an overaccumulation of K^+ . Nevertheless, the role of this type of transporters is largely underrepresented in literature. In comparison to our very good knowledge about K^+ channels and K^+/H^+ symporters, the information about K^+/H^+ antiporters in plants is rudimentary (see e.g. Isayenkov et al., 2020 for a recent review). The analyses presented in this study may explain why. Functionally, there was no difference between electroneutral ($n_a = 1$) and electrogenic ($n_a > 1$) K^+/H^+ antiporters. In the physiological range, both accomplished the same tasks. Nevertheless, systems with electrogenic K^+/H^+ antiporters consumed more energy than systems with electroneutral antiporters indicating that optimised organisms like plants would likely employ the electroneutral form. Electroneutral transporters, however, are hardly detectable in standard electrophysiological experiments and therefore extremely difficult to characterise. Thus, the mere fact that $V < E_K$ is often observed in a plant cell strongly suggests the existence of electroneutral K^+/H^+ antiporters on the basis of the thermodynamic considerations in this study.

It was surprising for us how many fundamental conclusions can be drawn in an airtight manner, without approximations, by applying basic thermodynamics and mathematics to plant biology. The discovery of homeostats enabled a new perspective on membrane transport in plants. And with the considerations presented here for K homeostats, we may have facilitated to adapt this concept to any type of homeostat as already carried out for anions (Dreyer et al., 2022; Li et al., 2024), sugars (Dreyer, 2021a) and auxins (Geisler & Dreyer, 2024), for instance. In a follow-up tutorial study, we will present the analyses of the dynamics of the K homeostat, that is, how the system reacts when it is deflected from the steady state. We will present the mathematical background that describes when the K homeostat is brought out of steady state (i) by a readjustment of transporter activities (tuning of g_x values), (ii) by an external imbalance in the K^+ gradient or (iii) by an electrical stimulus. Here, too, the detour via mathematics and computer simulations allows far-reaching conclusions to be drawn about the fundamental physiological properties of the transporter network.

Supplementary materials. The supplementary material for this article can be found at <http://doi.org/10.1017/qpb.2024.8>.

Competing interest. The authors declare none.

Data availability statement. The authors confirm that the data supporting the findings of this study are available within the article and its [Supplementary Materials](#). Raw data sets are available from the corresponding author, I.D., upon reasonable request.

Author contributions. I.D. conceived the study. All authors contributed to the design of the study. I.D. conducted the data analyses. N.H.-R., Y.B.-H., V.T.-C., S.Z.A.-M., E.D.-P., F.M.-Q., F.V.-V., O.A.-S. and M.E.R.-M. participated in data visualisation. I.D., J.R. and E.M. wrote the first draft of the manuscript. All authors contributed to the editing of the manuscript and approved its final version.

Funding statement. This work was supported by the Agencia Nacional de Investigación y Desarrollo de Chile (ANID), grant no. 21220432 to F.M.-Q., no. 21220419 to F.V.-V. and Anillo-ANID ATE220043 (the multidisciplinary centre for biotechnology and molecular biology for climate change adaptive in forest resources; CeBioClif) to I.D. and by Fondo Nacional de Desarrollo Científico, Tecnológico y de Innovación Tecnológica (FONDECYT/Chile), grant no. 3190544 to M.E.R.-M., no. 1210920 to E.M. and no. 1220504 to I.D.
