Hakea sericeae Schrader and *H. salicifolia* (Vent.) B. L. Burtt. are perennials, which belong to the Proteaceae family. Native to dry tropical zones from South Australia, they became aggressive species, particularly in damaged, dried and windy areas and are now considered invaders in some places of mainland Portugal [1], [2]. With no natural predators, the use of chemical control is the main way to manage these plants but they both show a small foliar area, therefore usually little success has been achieved [3].

In this work we use light and scanning electron microscopy to observe their leaves morphoanatomy and try to understand possible reasons for that failure. Plant material was sampled from young leaves and from 1-2 year-old shoots in natural populations of *H. sericea* and *H. salicifolia*, during 2006-2007, near Pedrogão Grande and Serra de Sintra, respectively. Plant material was prepared following the usually procedures [4].

Although their leaf morphology is quiet different, *H. sericeae* has acicular leaves and *H. salicifolia* lanceolate leaves, they present some microcharacters in common. Transverse sections of *H. sericea* show an epidermis with a thick cuticle, between 12-18 µm in young leaves and 20-30 µm in older leaves. *H. salicifolia* cuticle varies between 3-5 µm in young leaves and 5-18 µm in older leaves. The two taxa present sunken stomata below the epidermal surface, always overarched by cuticular ridges and a pre-stomatal chamber (Fig. 1A). Calcium oxalate crystals as raphids appear only on epidermal cells of *H. sericea* (Fig. 1B). In both species the mesophyll tissue is composed of 1-2 layers of palisade parenchyma. Inserted in between are osteosclereids, bone shaped sclereids with columnar middles and small enlargements at both ends (Fig. 1A). In *H. salicifolia* older leaves with 360-450 µm wide, the osteosclereids can reach 100-250 µm long, while in *H. sericea* they only reach 100-200 µm long, in leaves with 1820-2080 µm diameter. In *H. sericea* the vascular organization resembles to a monocot atactostele, with vascular bundles randomly scattered and a well-developed sclenchymatous bundle sheath surrounding each vein. *H. salicifolia* presents a more typical eudicot leaf anatomy, although palisade parenchyma is the only type seen and vessels also show a bundle sheath, less notorious when compared with those found in *H. sericea*.

H. sericeae and *H. salicifolia* both possess xeromorphic adaptations, less notorious in young leaves, but strongly expressed in the old leave's morphology and anatomy. These adaptations are usually correlated with dry habitats but also with the absence of certain nutrients in the soil [5-6]. The reduction of leaf area, the increased thickness of cuticle and the sunken stomata, can contribute to a reduction in the rate of water loss and may also play a key role in its chemical control by slowing the absorption of herbicides or even, preventing it. This is in accordance with studies on other plant species [7]. The presence of osteosclereids in the leaves may be explained as a requirement for support because turgor pressure can not be maintained at high levels within tissues. But sclerophily

has also been related with long-lived leaves, which is the case of both *H. sericeae* and *H. salicifolia*. Calcium oxalate crystal formation in plants appears to play a central role in a variety of important functions, including tissue calcium regulation, protection from herbivory, tissue support, light gathering and reflection, and metal detoxification [8].

These results elucidate us about the leaf morphoanatomy in these taxa and also help us to understand the unsucces of their chemical control. To overcome this, attention must be paid to the plant's age and phenology, before the use of herbicides.
