(Received 10 May 2006 – Revised 4 October 2006 – Accepted 10 October 2006)

Soyabean meal (SBM)-induced enteritis in the distal intestine of the teleost Atlantic salmon (*Salmo salar* L.) and other salmonids may be considered a model for diet-related mucosal disorders in other animals and man. The role of the intestinal microbiota in its pathogenesis was explored. Compared to diets containing fishmeal (FM) as the sole protein source, responses to extracted SBM or the prebiotic inulin, with or without oxytetracycline (OTC) inclusion, were studied following a 3-week feeding trial. Intestinal microbiota, organosomatic indices and histology, as well as immunohistochemical detection of proliferating cell nuclear antigen (PCNA), heat shock protein 70 (HSP70) and caspase-3-positive cells in the distal intestine, were studied. Distal intestine somatic indices (DISI) were higher in inulin and lower in SBM compared to FM-fed fish. The low DISI caused by SBM corresponded with histological changes, neither of which was affected by OTC, despite a significant decrease in adherent bacteria count. Image analysis of PCNA-stained sections showed a significant increase in the proliferative compartment length in SBM-fed fish, accompanied by apparent increases in reactivity to HSP70 and caspase-3 along the mucosal folds, indicating induction of cellular repair and apoptosis, respectively. Fish fed the SBM diet had higher total number as well as a more diverse population composition of adherent bacteria in the distal intestine. Thus SBM-induced enteritis is accompanied by induction of distal intestinal epithelial cell protective responses and changes in microbiota. Putative involvement of bacteria in the inflammatory response merits further investigation.

Inflammation: Enteritis: Mucosal disorder: Diet: Intestine

The large surface area of the gastrointestinal tract is constantly bombarded by environmental antigens from the diet and microorganisms. The mucosal defence system must protect the body from pathogens and at the same time develop oral tolerance to antigens from the diet and commensal microbiota (see review by Chehade & Mayer, 2005). In man, gut mucosal disorders such as coeliac disease exemplifies loss of oral tolerance to a specific dietary antigen (gluten) whereas inflammatory bowel disease and Crohn's disease may represent loss of tolerance to the gut's microbiota. Histologically, severe cases include villous atrophy in coeliac disease and transmural ulceration in inflammatory bowel disease and Crohn's disease, as well as infiltrations of immune cells in the lamina propria in all three disorders (Fenoglio-Preiser *et al.* 1999). The aetiology and pathogenesis of these disorders are often complicated, involving genetic susceptibility, immune status, antigen dose and form, gut microbiota, and/or age of host at the time of exposure (Chehade & Mayer, 2005).

An added dimension in the study of diet–gut interactions are the effects of prebiotics, non-digestible food ingredients, mostly from plants, that promote gut and host health by selectively stimulating the growth and/or activity of one or a limited number of beneficial bacterial species already resident in the intestine (Gibson & Roberfroid, 1995; Grittenden & Playne, 1996; Bauer *et al.* 2006). These may produce an environment unfavourable to the growth of pathogens. Inulin (IN), as an example, is a set of fructans, with monomers linked by β (2-1) bonds (Roberfroid *et al.* 1998; Pool-Zobel *et al.* 2002), extracted from the chicory root (*Cichorium intybus*). The β (2-1) linkage cannot be hydrolysed by pancreatic or brush border digestive enzymes in the proximal intestinal tract of man and domestic animals (Pool-Zobel *et al.* 2002). It is fermented in the large intestine or colon (Roberfroid, 2002; Flickinger *et al.* 2003) by beneficial bifidobacteria and other lactic acid-producing bacteria, enhancing their relative populations (Pool-Zobel *et al.*

Abbreviations: DISI, distal intestine somatic index; FM, fishmeal; IN, inulin; OTC, oxytetracycline; SBM, soyabean meal; PCL, proliferative compartment length; PCL_{BL}, PCL corrected for body length; PCNA, proliferating cell nuclear antigen; HSP, heat shock protein; TVC, total viable count.

* **Corresponding author:** Dr Anne Marie Bakke-McKellep, Norwegian School of Veterinary Science, fax +47 22 59 73 10, email anne.mckellep@veths.no

2002). Furthermore, its use as dietary fibre in man offers other potential health benefits, such as reduction in risk of colonic diseases, insulin-independent diabetes, obesity, osteoporosis and cancer (Grittenden & Playne, 1996; Flickinger *et al.* 2003), blood cholesterol reduction, immune stimulation and enhanced vitamin synthesis (Jenkins *et al.* 1999).

In a teleost model of an intestinal mucosal disorder, full-fat and extracted soyabean meal (SBM), considered promising alternative protein sources to the traditionally used fishmeal (FM) in formulated salmonid diets, cause an inflammatory response in the distal intestine of Atlantic salmon (*Salmo salar* L.) and rainbow trout (*Oncorhynchus mykiss* Walbaum), putatively a hypersensitivity reaction pathohistologically similar to that of coeliac disease (van den Ingh & Krogdahl, 1990; van den Ingh *et al.* 1991, 1996; Rumsey *et al.* 1994; Baeverfjord & Krogdahl, 1996; Nordrum *et al.* 2000; Buttle *et al.* 2001; Krogdahl *et al.* 2003). The condition is accompanied by decreased growth as well as nutrient digestibility and absorption (Olli *et al.* 1994; Olli & Krogdahl, 1995; Nordrum *et al.* 2000; Krogdahl *et al.* 2003) and a possible negative effect on disease resistance (Krogdahl *et al.* 2000). Bakke-McKellep *et al.* (2000) suggested that the differentiation of distal intestinal epithelial cells is affected and may be the cause of many of the pathophysiological responses observed. Olli & Krogdahl (1995) and van den Ingh *et al.* (1996) concluded that alcohol-soluble components in the soyabean appear to be responsible for the negative effects of SBM, confirmed by the favourable results observed with soyabean concentrate (Olli *et al.* 1994; Krogdahl *et al.* 2000).

Recently, two investigations have evaluated the effect of SBM-based diets on gut microbiota of Atlantic cod, *Gadus morhua* L. (Ringø *et al.* 2006c), and rainbow trout in fresh water (Heikkinen *et al.* 2006). However, the possible involvement of microbiota in the pathogenesis of the SBM-induced enteritis in salmonids has not been investigated. On the other hand, some information is available on intestinal pathology of Arctic charr (*Salvelinus alpinus* L.) fed IN (Olsen *et al.* 2001). These pathological changes may be related to alterations in gut microbiota (Ringø *et al.* 2006b). Based on the evidence from mammals, possible sequelae of altered microbiota composition can include loss of normal signalling necessary for intestinal barrier function, resulting in loss of immune tolerance to commensal bacteria, or loss of inhibition of pathogenic bacteria by non-pathogenic commensals (Hooper & Gordon, 2001). In animal models of ulcerative colitis, animals raised in germ-free environments do not develop disease (Hanauer, 2004). Direct evidence for these relationships in fish is lacking.

The goal of the current study was to supplement the information that already exists on the intestinal pathology of Atlantic salmon, comparing the effects brought about by dietary SBM with those putatively caused by IN in the diet and to evaluate the contribution of the intestinal microbiota to the inflammatory response to each of these components. Therefore, oxytetracycline (OTC), a broad-spectrum antibiotic, was included in the experimental diets to reduce and/or eliminate pathogenic as well as opportunistically pathogenic microbiota. When examining the effects of these dietary factors, three critical features of tissue response following injury were addressed: (1) mobilization of heat shock protein (HSP), reflecting cell repair as well as protective measures and inhibiting apoptosis up to a 'point of no return' (HSP70

proteins); (2) apoptosis (caspase-3); and (3) cell regeneration (proliferating cell nuclear antigen; PCNA), as manifested in the size of the proliferative compartment.

Experimental methods adopted

Diets, animals and experimental design

Six experimental diets (Table 1) were formulated to contain: (1) a reference diet based on FM; (2) a diet in which 250 g de-hulled, extracted and toasted SBM/kg diet partially replaced FM and extruded wheat; or (3) a diet in which indigestible 75 g IN/kg diet partially replaced extruded wheat. Each diet was formulated with and without 3 g OTC/kg diet. Diets were formulated to be iso-nitrogenous and iso-energetic on a crude protein and gross energy basis, and to contain 20–21 % lipid and 54 % crude protein (on a DM basis). They were supplemented with standard vitamin and mineral premixes. The SBM diets were supplemented with crystalline DL-methionine and fish oil to equal the content of methionine and *n*-3 fatty acids, respectively, in the other diets. Diets were cold-pelleted with a pellet size of 3 mm.

The experiment was conducted in accordance with laws and regulations that control experiments and procedures in live animals in Norway, as overseen by the Norwegian Animal Research Authority. At AKVAFORSK Research Station, Sunndalsøra, Norway, groups of thirty-seven Atlantic salmon (individual mean fish weight 172 (SEM 1) g) were randomly distributed to each of twelve fibreglass tanks supplied with seawater (surface area 1 m²; depth 50 cm; 8–10°C). The fish were allowed a 14 d adaptation period following distribution, during which they were fed the reference FM diet (Table 1). During the subsequent 3-week feeding trial, randomly selected, duplicate tanks of fish were fed one of six experimental diets. The final model gave a 3 × 2 × 2 design, with diet and OTC as independent variables. Fish were continuously fed by automatic disc feeders. The growth rate was expected to be 1 % of body weight/d, and the fish were fed 15 % more than the expected need, assuming a feed conversion of 1.0 (Austreng *et al.* 1987). The feed intake appeared good when judged by visual observation. The water temperature during the experiment ranged from 8 to 10°C, and the O₂ saturation of the outlet water was above 80 %.

Sampling

All fish were euthanized in water with a lethal concentration of tricaine methanesulphonate (MS 222; Argent Chemical Laboratories, Redmond, WA, USA) and individually weighed and measured. Randomly selected fish from each tank were sampled for different analyses.

For calculation of organosomatic indices, the gastrointestinal tracts of five fish per tank were removed and divided into four sections: stomach, pyloric region, mid intestine (section between the distal-most caecum and the increase in diameter indicating the start of the distal intestine) and distal intestine (from the distal end of the mid intestine to the anus). Intestinal contents and adherent adipose and connective tissue were carefully removed. Samples were placed in tared tubes, frozen in liquid nitrogen and stored at –80°C until weighing.

For histological evaluation and immunohistochemical analyses of markers for cellular proliferation (PCNA), programmed cell death or apoptosis (caspase-3) and stress-related protein degenerative and/or regenerative processes (HSP70), three fish per tank were sampled. Gastrointestinal tracts were removed, prepared as described earlier, and samples of mid and distal intestines (5 × 5 mm each) fixed in neutral buffered formalin (4%, pH 7.2) for 24 h and subsequently stored in 70% ethanol. Additional samples of distal intestine were frozen in liquid propane chilled with liquid nitrogen and stored at –80°C until immunohistochemical analyses could be performed.

Adherent and non-adherent bacteria from the mid and distal intestine were isolated from three additional fish per tank as previously described (Ringø, 1993). Briefly, the gastrointestinal tract was dissected as described earlier and the contents (digesta) from the mid and distal intestine were transferred to sterile plastic bags. The corresponding intestines were thoroughly rinsed three times in 2 ml sterile 0.9% saline to remove non-adherent bacteria and likewise transferred to separate sterile plastic bags.

Histological screening of intestinal tissue

Samples for histological analysis were processed according to standard histological methods (Histological Laboratory, Norwegian School of Veterinary Science). Sections approximately 5 µm thick were cut parallel to the longitudinal direction of the intestine, in the distal intestine perpendicular to the macroscopically visible circular folds (complex folds), and stained with haematoxylin and eosin. Intestinal samples were scored based on morphological changes described by Baeverfjord

& Krogdahl (1996). Mid intestine scores were based on evaluation of widening and cellular infiltration of the lamina propria, and degree of enterocyte vacuolization. Lamina propria scores (0–3) were assigned as: 0, normal; 1, mild; 2 moderate; 3, marked widening and infiltration. Enterocyte vacuolization scores (0–1) were: 0, slight vacuolization; 1, no vacuolization. Half (0.5) points were included. Total mid intestine scores were classified as: 0–1, normal; > 1–3, moderate pathological changes; > 3–4, severe change. Distal intestine scores were based on evaluation of the lamina propria, enterocyte vacuolization and mucosal fold height. Lamina propria scores were assigned similarly as mid intestine scores. Enterocyte vacuolization scores (0–3) were: 0, highly vacuolated; 1, mildly reduced; 2, moderately reduced; 3, markedly reduced (absence). Mucosal fold height scores were: 0, normal (long); 1, medium; 2, short. Half (0.5) points were included. Total scores of distal intestine were classified as: 0–1, normal; > 1–5, moderate pathological change; > 5–8, severe change.

Immunohistochemistry

The immunohistochemical protocol given later represents the result following a series of laboratory tests, including comparison between cryostat and formalin-fixed paraffin sections and various de-masking procedures of paraffin sections. Thus, we arrived at three different procedures corresponding to the particular antigen that was to be detected: PCNA, caspase-3 and HSP70. With respect to caspase-3 and HSP70, formalin-fixed paraffin sections were used. For PCNA, cryostat sections were used. The cryostat sections of 7 µm in thickness were cut as described earlier, placed on glass slides, thawed and air-dried for 1 h before fixation in 4% buffered formalin for 2 min and

70% alcohol for 10 min. With respect to the paraffin-embedded sections for caspase-3 and HSP70, sections were subjected to deparaffinization using xylene at 58°C and subsequent rehydration. For HSP70, de-masking of the sections was done by hydrated autoclaving at 121°C for 15 min in 0.01 M-citrate buffer pH 6.0. For caspase, de-masking of sections was done by treatment with 1 mg/ml trypsin (No. 215230; Difco, BD Biosciences, Sparks, MD, USA) in a 0.1 M-Tris-HCl buffer, pH 8.0 at 37°C for 40 min. To inhibit endogenous peroxidase, the sections were treated with phenyl hydrazine (Fluka, Buchs, Switzerland), 0.05% PBS for 40 min at 37°C. To avoid non-specific binding, sections were incubated for 20 min with 5% bovine serum albumin in Tris-buffered saline containing normal goat serum diluted 1:50.

Primary antibodies included a rabbit polyclonal antibody against caspase-3 (Anti-ACTIVE® Caspase-3 pAb, No. G7481; Promega, Southampton, UK), a mouse monoclonal anti-HSP70 (clone BRM-22, No. H5147; Sigma-Aldrich, Oslo, Norway) and a mouse monoclonal anti-PCNA (α -PCNA, clone PC10, No. M0879; Dako, Glostrup, Denmark). An indirect immunoperoxidase method (EnVision® System, Peroxidase; Dako) was used for immunohistochemistry. The labelling was performed according to the manufacturer's instructions with some modifications. The blocking solution was removed and the sections were incubated with the primary monoclonal antibodies for 30 min. Between each step in the procedure, apart from the blocking step, the sections were washed three times with PBS for 5 min. The incubation time for the secondary antibody, peroxidase-labelled polymer conjugated with goat anti-mouse or, as appropriate, anti-rabbit Ig, was 30 min. All incubations took place in a humid chamber at room temperature. The peroxidase activity was detected with a 3-amino-9-ethylcarbazole kit from Dako (No. K4008), for 20 min. The sections were counterstained either with haematoxylin for 1 min or with methyl green (No. S1962; Dako) and mounted with polyvinyl alcohol under a coverslip before examination. Control sections were incubated with 1% bovine serum albumin in Tris-buffered saline instead of the primary antibody.

Data-assisted image analysis

Cryostat sections stained for PCNA and counterstained with methyl green, as described earlier, were examined by light microscopy (Leica DM RXA microscope; Leica Microsystems AG, Wetzlar, Germany). Digital images of each section were taken with a Spot RT Slider digital camera (Diagnostic Instruments Inc., Sterling Heights, MI, USA), utilizing the Spot Image Capture Software, version 3.0.4 (Diagnostic Instruments Inc.). Digital images taken at 200 \times magnification were used for morphometric measurement using morphometric software ImagePro Plus, version 4.5 (Media Cybernetics, Silver Spring, MD, USA). Groups of adjacent epithelial cells located in the basal (proliferative compartment) areas of the simple mucosal folds (as opposed to the complex folds) that stained positively for PCNA were measured (μ m). Proliferative compartments that appeared closed off to the lumen or circular were excluded since this was an indication that the tissue or parts of the tissue had been sectioned obliquely.

From each section, sixteen to thirty-seven proliferative compartments were measured (means 26, 23 and 28 from

FM, IN and SBM, respectively). The mean PCNA-positive proliferative compartment length (PCL) was calculated using all measurements of PCNA-positive compartments in each section. In order to reduce variation due to differences in fish size, PCL was corrected for body weight and body length.

Bacteriology

Mid and distal intestinal segments and their respective digesta were homogenized in a Stomacher (Seward Laboratory, London, UK). Homogenates of the intestinal segments and the digesta were diluted in sterile 0.9% saline and appropriate dilutions spread on the surface of tryptic soya agar (Difco) plates (with 5% glucose and 1% NaCl added). The plates were incubated at 12°C and inspected regularly for up to 4 weeks. After enumeration (Ringø, 1993), a representative selection of colonies, 1320 autochthonous (adherent) and allochthonous isolates were subcultured until purity was achieved. Whenever necessary, the isolates were tested for up to fifty-two biochemical and physiological properties as shown by Ringø & Olsen (1999). One hundred strains isolated from each rearing group were further characterized by sequencing the 16S rRNA gene.

DNA was extracted from selected isolates by the method described by Pitcher *et al.* (1989). The pellet was resuspended in 100 μ l deionized water, and the concentration of DNA was determined spectrophotometrically at wavelength 260 nm. The DNA was stored at -20°C until analysis.

PCR amplifications of the 16S rRNA genes were performed using the forward primer 27F (AGAGTTTGTATCMTGGC-TCAG) and the reverse primer 1491R (GGTACCTTGTTA-CGAC TT). A detailed description is given by Ringø *et al.* (2006b). The amplicons were digested with the 4 bp restriction enzyme HaeIII (New England Biolabs, Ipswich, MA, USA). Direct sequencing of PCR products was performed with 27F as the sequencing primer. The cycle-sequencing reaction was performed in a GeneAmp PCR System 2400, and labelled fragments were separated on a 310 Automated Genetic Analyzer (Applied Biosystems, Oslo, Norway), both procedures according to the manufacturer's protocols (Applied Biosystems). The partial sequences of the 16S rRNA gene were analysed and edited using BioEdit. An initial BLAST-search in GenBank retrieved the taxonomic groups for which they showed the highest identities. For each sequence, an alignment was constructed with all members of the group. Phylogenetic inference by the neighbour-joining method was performed using the PHYLIP package bootstrap. The species with the closest phylogenetic relationship with the isolate was identified and selected for more comprehensive analyses. The twenty-nine sequences corresponding to the bacterial isolates and twenty-one sequences from GenBank were aligned with ClustalW in the BioEdit package.

Calculations

Organosomatic indices were calculated as follows:

$$\begin{aligned} \text{Organosomatic index(\%)} \\ = [\text{tissue weight(g)}/\text{body weight(g)}] \times 100. \end{aligned}$$

Distal intestine somatic index relative to body length

$$(\text{DISI}_{\text{BL}}; \text{g}/100\text{cm}) = [\text{distal intestine weight (g)}/\text{fork length (cm)}] \times 100.$$

PCNA values were calculated as follows:

$$\text{PCNA} - \text{positive PCL corrected for body length} \\ (\text{PCL}_{\text{BL}}; \mu\text{m}/\text{m}) = [\text{PCL} (\mu\text{m})/\text{body length (cm)}] \times 100.$$

Statistical analysis

Statistical analyses were conducted using SAS statistical software, version 8.02 (SAS Institute Inc., Cary, NC, USA). Two-way ANOVA (general linear model) was performed with diet and OTC supplementation as class variables. Intestinal region was included as a third class variable (three-way ANOVA) for analysis of total bacterial population levels. When interactions were not significant marginal means were compared using Duncan's multiple range tests. When interactions were significant, *post-hoc* pair-wise comparisons (LSMEANS/PDIFF procedure) were used to compare differences within each combination of class variables. The level of significance was established at $\alpha = 0.05$ for all tests. All analyses were performed on tank means (means of all sampled fish per tank) except microbial analysis, which was performed on means of six fish per treatment. Data for microbial analysis were log transformed prior to statistical analysis.

Results

No mortalities occurred during the feeding trial. Growth effects were not a goal of the present study, and the duration of the feeding period was too short for accurate evaluation of an effect on growth. Diet effects are presented first, with OTC inclusion and interactions between diet and OTC following for the various parameters.

Body parameters

Diet did not significantly affect body weight or body length. Irrespective of OTC inclusion, final mean weights were 243 (SEM 7), 238 (SEM 2) and 237 (SEM 2) g, and final mean lengths (fork length) were 26.7 (SEM 0.2), 26.5 (SEM 0.8) and 26.5 (SEM 0.0) cm for FM, SBM and IN diets, respectively (four tanks per diet).

OTC inclusion did not affect body weight or body length significantly. Irrespective of diet, final mean weights were 241 (SEM 4) and 237 (SEM 2) g, and final mean lengths were 26.6 (SEM 0.1) and 26.5 (SEM 0.1) cm for diets without and with OTC, respectively (six tanks per OTC inclusion level). No interaction between diet and OTC inclusion was observed.

Organosomatic indices

Diet did not affect stomach, pyloric caeca or mid intestinal somatic indices significantly (Table 2). During sampling the distal intestine of the SBM-fed fish appeared macroscopically more translucent, indicating a thinner intestinal wall. Fish fed SBM diets had a lower DISI compared to FM-fed fish, while IN-fed fish had a higher DISI (Table 2). The estimation of the DISI corrected to equal body length showed the same statistical pattern as the DISI corrected to body weight. OTC supplementation did not affect any of the organosomatic indices significantly. Interaction between OTC and diet was not observed either.

Histological screening of intestinal tissue

Few fish (one, two and two fish fed FM, SBM and IN diets, respectively) showed changes in the enterocyte columnar epithelium and lamina propria of mid intestinal sections. Statistical analysis did not reveal significant effects of the diet on histological scores (Table 3). However, the mid intestine of six of twelve SBM-fed fish and six of twelve IN-fed fish showed moderate leucocytic cell infiltration of the muscular layers.

* For details of procedures, see pp. 699-700.

† Maximum score = 4.

‡ Maximum score = 8.

Of the five fish that showed changes in the enterocyte columnar epithelium and/or lamina propria of the mid intestine, two were fed OTC-free diets and three were fed OTC-supplemented diets. OTC inclusion did not affect histological scores; however, the overall model *P* value was nearly significant (*P* = 0.0695) due to the interaction term (diet × OTC supplementation). The leucocyte infiltration of the muscular layers occurred in eight of eighteen fish fed OTC-free diets and four of eighteen fish fed OTC-supplemented diets.

All fish fed the FM diets and eleven of twelve fish fed the IN diets showed normal morphology of the distal intestine, characterized by the presence of well-differentiated enterocytes with many absorptive vacuoles, though there appeared to be increased vacuolization in fish fed IN diets. In contrast, moderate and marked morphological changes were observed in all fish fed the SBM diet. Morphological changes included variable degrees of mixed leucocyte cell infiltration, including eosinophilic granular cells, of the lamina propria and reduced vacuolization of the enterocytes, and shortening of mucosal folds (Fig. 1). Feeding SBM resulted in a significantly higher histological score than feeding FM or IN (Table 3). No significant difference was observed between the FM and IN diets. Neither OTC supplementation nor interaction affected histology scores.

Immunohistochemistry of the distal intestine

As antibodies against PCNA, HSP70 and caspase-3 in salmon are unavailable, the antibodies developed against mammalian antigens were evaluated initially based on their assumed pattern of reactivity within tissue sections of controls. Thus, the antibody against PCNA reacted against a population of dividing epithelial cells at the base of the mucosal folds as expected (Fig. 2). Likewise, antibodies against caspase-3 reacted against epithelial cells close to the tips of the complex and

simple folds (Figs 3 and 4). Sometimes reactivity was seen in cells extruded from the epithelium, corresponding to the expected extrusion following senescent apoptosis. As the applied antibodies against HSP70 are claimed to detect constitutive as well as inducible members of the HSP family in a wide spectrum of mammals (compare product description earlier), a predictable pattern of reactivity of this antibody was less obvious. As it turned out, the reactivity was confined to the upper 10–20% of the folds, and in some folds apparently was absent (Fig. 3). A population of epithelial cells at the tips of the complex folds appeared to react more consistently. At the cellular level, reactivity was seen in the nucleus as well as in the cytoplasm, although not always in both sites.

When the different diets were compared, OTC inclusion had no apparent effect on the findings mentioned earlier. Therefore only groups fed the diets not containing OTC were analysed more thoroughly for HSP70 and caspase-3 reactivity. A change of reaction pattern was observed as a response to SBM, in which the SBM diets caused an increase in the PCNA-positive proliferative compartment at the base of the folds (Fig. 2), accompanying a marked enhancement of HSP70 and caspase-3 reactivity in epithelial cells at the tips of the simple folds (Figs 3 and 4). In contrast, and as emphasized earlier, epithelial cells at the tips of the complex folds sometimes showed reaction even in the controls, albeit less extensively than in SBM-fed fish.

Digital image analysis confirmed that SBM caused a significant increase in PCL at the base of the folds compared to fish fed FM and IN diets (Table 3). No difference was found between FM and IN diets. PCL_{BL} was also affected by diet. Fish fed the SBM diet had a significantly higher PCL_{BL} than fish fed FM and IN diets, but the FM and IN treatments were not significantly different. Fish fed diets containing OTC had lower PCL_{BL} than fish fed diets without OTC, but no interaction between diet and OTC inclusion was observed.

Fig. 1. Distal intestinal histology (haematoxylin and eosin) of fish fed (A) fishmeal (FM), (B) soyabean meal (SBM) and (C) inulin (IN) diets ($\times 400$). e, epithelial layer; gc, goblet cell; lp, lamina propria; v, absorptive vacuoles.

Bacteriology

Diet, OTC and intestinal region affected intestinal bacterial population levels (Table 4) and all interactions were statistically significant. In order to present results in a concise and meaningful manner only those that are biologically relevant are presented. Results are presented as the log of total viable count (TVC) of bacteria isolated from 1 g (wet weight) of tissue or digesta. The influences of diet and intestinal region and the interaction between them are presented for data of non-OTC-supplemented diets due to the confounding effect of OTC in the three-way interaction.

In fish fed diets without OTC, there was an overall trend of higher total bacterial levels in digesta (mean log 4.67 and 4.75 for mid and distal intestine, respectively) compared to adherent population levels (mean log 3.73 and 4.09, respectively). Population levels in mid and distal intestinal digesta did not differ significantly, but adherent population levels did (distal intestine > mid intestine). However, within specific diets, IN-fed fish had similar adherent and digesta levels in the mid as well as distal intestine, and FM-fed fish had higher

levels in digesta of the mid compared to distal intestine. In SBM-fed fish, higher digesta compared to adherent population levels were found in both intestinal regions. Overall, fish fed SBM diets had the highest bacterial population level (mean log 4.76), followed by FM (4.40) and IN (3.78). The orders of total bacterial population levels ranked by diet in each of the intestinal regions are shown in Table 4.

OTC inclusion significantly reduced total bacterial population levels across diets and intestinal regions from an overall mean log TVC of 4.31 to 2.36. OTC inclusion caused a greater reduction in bacteria from digesta than mucosa (approximately 500- and 10-fold log reductions, respectively). The greatest effect occurred in the distal intestine digesta (log TVC 1.55; reduction by log 3.20), followed by mid intestine digesta (2.39; reduction by 2.28). Adherent bacterial populations were also reduced but to a lesser extent: mid intestine, 2.05 (reduced by 1.68); distal intestine, 3.47 (reduced by 0.62). An exception was the large reduction in adherent bacteria in the mid intestine of the FM-fed group (0.24; reduced by 3.39). When OTC was included in the diet, the mean log TVC of SBM- and FM-fed fish did not differ significantly (2.65 and 2.77, respectively)

Fig. 2. Cryosections of salmon distal intestine, immunohistochemical detection of proliferating cell nuclear antigen (PCNA) in fish fed (A) fishmeal (FM), (B) soyabean meal (SBM) and (C) inulin (IN) diets. Antibody against PCNA reacted against a population of dividing epithelial cells at the base of the simple intestinal folds. SBM (B) caused a significant increase in the length of the proliferative cell compartment compared to fish fed FM (A) and IN (C) diets. f, mucosal folds; lu, lumen; pc, proliferative compartment.

Fig. 3. Formalin-fixed sections of salmon distal intestine, immunohistochemical detection of heat shock protein 70 (HSP70) and caspase-3. (A) Fish meal diet (FM), HSP70. Very scarce reactivity is seen in the absorptive epithelial cells (compare with (B)). (B) Soyabean meal diet (SBM), HSP70. The majority of the epithelial cells at the tips of the simple mucosal folds are reactive. (C) Fish meal diet (FM), anti-active caspase-3. Scarce reactivity is seen in the absorptive epithelial cells. (D) SBM, anti-active caspase-3. The epithelial cells at the tips of the folds are reactive. All sections counterstained with haematoxylin.

but were greater than in IN-fed fish (1.66). OTC had a greater effect on the reduction of total bacterial population levels in SBM- and IN-fed fish (reduction by 2.12 each) than in FM-fed fish (reduction by 1.63).

In total, 1320 adherent and allochthonous bacterial colonies were isolated from the digestive tract of Atlantic salmon. Traditional culture-based microbiology showed that the microbiota

Fig. 4. Formalin-fixed sections of salmon distal intestine, immunohistochemical detection of anti-active caspase-3. (A) Fish meal diet (FM) (control). In control salmon caspase reactivity (red) typically affects individual cells and probably represents senescent cells close to the tips of the simple folds. Note the reactive epithelial cells (\leftarrow). The staining is seen primarily in the nuclei. Due to the vacuolization that is typical for the absorptive epithelial cells in this segment of the intestine, the staining of cytoplasm is not always evident. (B) Soyabean meal diet (SBM). Most of the epithelial cells at the tip of this simple fold are reactive. Both cytoplasmic and nuclear staining is seen. (C) SBM. Most of the epithelial cells at the tip of this complex fold are reactive. Note the stretches with reactive (red) epithelial cells and the large number of leucocytes in the lamina propria, many of which are reactive. All sections counterstained with haematoxylin.

species profiles were different between the treatment groups, as clearly demonstrated in Fig. 5. Of the identified isolates, twenty-four genera and species were identified from fish fed FM (Table 5A) and twenty-six genera and species from fish fed

Fig. 5. Tryptic soya agar plates showing adherent bacteria isolated from the distal intestine of Atlantic salmon (*Salmo salar* L.) fed fish meal (FM) and soyabean meal (SBM) diets.

SBM (Table 5B), but only sixteen genera and species from fish fed IN (Table 5C). The bacteria *Nocardia corynebacteroides* and *Rathayibacter tritici* were exclusively found in the FM-fed fish; *Vibrio* spp., *Arthrobacter agillis*, *Brachybacterium* spp., *Kocuria carniphila* and *Rhodococcus* spp. were isolated only from the SBM-fed fish; whereas *Brevibacterium* and *Enterococcus* spp.

were isolated only from the SBM- and IN-fed fish. Interestingly, *Arthrobacter agillis*, *Kocuria carniphila* and *Rhodococcus* spp. were adherent bacteria found only in the distal intestine of the SBM + OTC group. The IN-fed fish lacked the presence of *Pseudoalteromonas* and *Micrococcus* spp., as well as several species of other genera identified in the other dietary groups. The numbers of isolated lactic acid species *Marinilactibacillus psychrotolerans* and *Carnobacterium piscicola* were higher in the digesta than adherent to the mucosa, and were higher in the FM-fed than in SBM- or IN-fed fish. *Enterococcus* spp., mostly *Enterococcus faecalis*, were not detected in the FM-fed fish, and their numbers were higher in the SBM- than IN-fed fish. In some cases, the total counts of viable bacteria were lower than the detection level when OTC was added to the diets (Table 4). Therefore, no adherent bacteria were identified from the mid intestine of fish fed the FM + OTC diet, the mid intestinal digesta of fish fed the IN + OTC diet, or from the distal intestinal digesta of fish fed the SBM + OTC and IN + OTC diets.

Discussion

The contribution of the intestinal microbiota to the pathological changes associated with SBM-induced enteritis in Atlantic salmon was investigated by calculating intestinal somatic indices, evaluating intestinal histology, the occurrence of HSP70 and caspase-3-positive cells, as well as PCNA-positive proliferative compartments at the base of the mucosal folds in the distal intestine, and characterizing the intestinal microbiota. The morphological characteristics of the inflamed distal intestine of the SBM-fed fish were in accordance with previous studies (van den Ingh *et al.* 1991, 1996; Baeverfjord & Krogdahl, 1996; Nordrum *et al.* 2000; Hemre *et al.* 2005) and the inclusion of 3 g OTC/kg to the SBM diet did not influence the development of the inflammation, as reflected by the histological scores and the pathophysiological responses measured.

Pathophysiological responses

The longer PCNA-positive PCL in the distal intestine of SBM-fed fish indicates a higher rate of cell renewal, likely a result of the inflammatory response (Wolf & Dittrich, 1992). Sanden *et al.* (2005) reported a similar response to SBM in Atlantic salmon parr. A reduction in the number of mature, developed enterocytes would explain the dysfunction previously observed in this intestinal region (Bakke-McKellep *et al.* 2000; Nordrum *et al.* 2000; Krogdahl *et al.* 2003). Various plant lectins consumed with the diet have also been shown to increase crypt cell proliferation as well as cause morphological changes in the intestine of rats (Banwell *et al.* 1993; Pusztai *et al.* 1995), although soyabean lectin has been ruled out, at least as a sole cause of SBM-induced enteritis in salmon (van den Ingh *et al.* 1996). The increased number of apoptotic cells and reduced DISI in SBM-fed salmon both

suggest a concomitant loss of cells, explaining the significant shortening of mucosal folds observed by Baeverfjord & Kroghdahl (1996) and further reducing the number of functional enterocytes. The remaining cells also appear to be responding to the unidentified 'stressor(s)' in SBM by attempting to regulate the apoptotic pathway and facilitate cellular recovery, as the increased number of HSP70-positive cells indicates. Thus, the HSP70 are characterized by high inducibility during inflammation, representing an attempt by the cell to avoid apoptosis by an antagonizing effect of HSP70 on cell death pathways (Calderwood *et al.* 2005).

IN did not induce damage to the intestinal mucosa of the salmon as reported in Arctic charr (Olsen *et al.* 2001), although we did note a qualitative increase in the vacuolization of IN-fed fish. The contrasting findings in charr may be due to differing dietary levels of IN (twice the level of the current study) or differing analytic methods (transmission electron microscopy). Olsen *et al.* (2001) reported changes in the organization of microvilli and the presence of intracellular lamellar bodies in distal intestine enterocytes. Light microscopy does not allow sufficient resolution to evaluate these structures. However, Olsen *et al.* (2001) also reported increased vacuolization of distal intestine enterocytes (measured as percentage of cell volume). Therefore, the effect of IN, including possible beneficial effects, in Atlantic salmon diets merits further study.

The increased DISI in IN-fed fish appeared to be the result of hypertrophy of the muscularis externa. Greger (1999) reported similar hypertrophy of the caecal wall in rats fed IN, possibly caused by increased peristaltic activity.

The current study suggests that OTC inclusion results in a decrease in the rate of cellular proliferation in the distal intestinal proliferative compartments of Atlantic salmon. This is in accordance with the known action of tetracyclines, specifically inhibiting not only bacterial but also somatic cell mitochondrial protein synthesis. The resulting lack of oxidative ATP-generating capacity causes proliferation arrest of normal and malignant cells of epithelial origin (van den Bogert *et al.* 1986).

The digital image analysis employed to quantify the PCNA-positive areas is presented here for the first time. Earlier methods of analysis in mice (Muskhelishvili *et al.* 2003) and fish (Ortego *et al.* 1994; Berntssen *et al.* 2001, 2004; Hemre *et al.* 2004; Sanden *et al.* 2005) differ significantly compared to the current study. The previous studies calculated proliferation indices (% of total cells that stained positively for PCNA) either in a defined area, from a defined number of cells or along the entire crypt-villus length. A disadvantage of these types of measurements is that they are highly time consuming. Additionally, these methods do not consider the reduction in the height of villi (or mucosal folds), as observed in SBM-fed fish, a factor which may reduce the reliability of row counts as estimators of villus

cell populations (Alison, 1995). The method used in the current study also allows measurement of areas in which individual cells cannot be discerned.

Bacteriology

Bacterial involvement in the pathogenesis cannot be excluded despite efforts to rule this out in the current study. Although OTC was effective in reducing bacterial numbers, in accordance with previous investigations in various fish species (Austin & Al-Zahrani, 1988; Sugita *et al.* 1988; Kerry *et al.* 1997), the lack of effect on the inflammatory response suggests that: (1) microbiota had no influence on SBM-induced enteritis in salmon in the present study; (2) the concentration or activity of OTC was decreased by the time it reached the epithelium of the distal intestine so it could not sufficiently reduce numbers of potentially key adherent bacteria; (3) the alteration in the species composition of the microbial community was important (see later); and/or (4) the absence of microbiota in the digesta of the SBM + OTC-fed salmon may directly or indirectly have a similar detrimental effect on the intestine as the SBM. The second point may be substantiated by the absence of adherent bacteria in the more proximally located mid intestine versus the distal intestine of FM-fed fish treated with OTC. Physical properties of the digesta as influenced by feed ingredients, such as viscosity and pH, may also have adversely influenced OTC's activity or ability to reach the epithelium. In future studies, inclusion of higher levels of OTC may therefore lead to a different result. Concerning the third point mentioned earlier, further investigation of the possible influence of *Psychrobacter*, *Enterococcus*, *Micrococcus* and *Staphylococcus* spp. in the pathogenesis of SBM-induced enteritis merits study since these were adherent bacteria in the distal intestine that were reduced but not eliminated by OTC. Furthermore, the role of other adherent bacteria present in the distal intestine of the SBM + OTC-fed group, but not in the SBM or other dietary groups, merit study as possible (facilitative) pathogens: *Arthrobacter agillis*, *Kocuria carnophila* and *Rhodococcus* spp. These may have been resistant to the OTC and/or their proliferation allowed by the suppressed population growth of other species, including those present in the digesta, caused by the addition of the antibiotic. Concerning the fourth point, the absence of microbiota in the digesta of not only the distal but also the mid intestine of the IN + OTC-fed fish did not result in histological changes. Most likely this rules out the possibility of any deficiency of microbially produced nutrients or metabolites as a potential cause of histological changes.

From the current study it is apparent that fish fed the SBM diet had an altered microbial population profile compared to FM- or IN-fed fish. By using soya agar (containing peptone from SBM) when culturing the bacteria we cannot rule out a certain selective effect that might have resulted in the larger diversity of the bacteria observed in the SBM-fed fish than in the other dietary groups. Nevertheless, the higher nitrogen-free extract fraction (indigestible carbohydrates) of the SBM-containing diets compared to FM, as well as soyabean's content of the non-digestible oligosaccharides stachyose and raffinose may also have contributed to this. In single-stomached higher vertebrates, studies have shown that these components may result in a greater

bacterial diversity (Konstantinov *et al.* 2003, 2004) and an increase in the number of bifidobacteria and/or lactobacilli (Ross *et al.* 1983; Jonsson & Hemmingsson, 1991; Okubo *et al.* 1994; Dongowski *et al.* 2002; Guo *et al.* 2004; Tzortzis *et al.* 2004). This latter finding, however, was not the case in the present study in which the highest levels of lactic acid bacteria were observed in the FM-fed salmon. The more diverse microbial community found in the SBM-fed salmon may also influence or be influenced by nutrient availability or utilization. Previous studies have repeatedly demonstrated lower macronutrient digestibilities when salmon are fed SBM (Olli *et al.* 1994; Olli & Krogdahl 1995; Krogdahl *et al.* 2003). However, possible changes in levels of microbial metabolites – whether potentially beneficial, such as SCFA; or detrimental, such as ammonia, amines or amides – have not been studied.

Interestingly, the present results clearly showed that inclusion of 7.5 % IN in the diet led to less diverse microbiota colonizing the gut. The present results are in accordance with a study on Arctic charr (Ringø *et al.* 2006b) but contradict findings in mammals (Gibson & Roberfroid, 1995; Pool-Zobel *et al.* 2002; Xu *et al.* 2002). The reason for this has not been elucidated, but we suggest that IN has a selective effect on Atlantic salmon and Arctic charr gastrointestinal microbiota. Whether this effect is also valid for other fish species and whether it has a beneficial or detrimental effect on fish health remains to be studied.

When evaluating the intestinal microbiota of fish, a major question arises: does the intestinal microbiota have any beneficial nutritive or health effect? During the last decade several investigations have attempted to evaluate whether the gut microbiota are able to inhibit growth of pathogenic bacteria *in vitro* (Gatesoupe, 1999; Ringø *et al.* 2005). It is generally accepted that the gastrointestinal tract of fish is an important route of infection (Birkbeck & Ringø, 2005). Whether the dietary manipulations observed in the present study have any effect on colonization of pathogens in the gastrointestinal tract, or a protective effect in challenge studies, is not known, and these scientific challenges are worth investigating. Other studies of interest include the contribution of the gut microbiota to fish nutrition, nutrient availability and assimilation as well as their influence on nitrogen metabolism in the intestine of fish with the possibility of reducing ammonia excretion. In both cases, dietary manipulation and prebiotics may have beneficial effects as indicated by studies with higher vertebrates (see review by Bauer *et al.* 2006). The present study suggests that the significance of the gut microbiota in salmon, carnivorous animals heavily influenced by their seemingly inhospitable marine, cold-water environment, may be greater than previously assumed.

Long-term incubation under conditions conducive to those found *in vivo* in a marine poikilothermic organism, and identification based on a combination of various biochemical and physiological analyses as well as by sequencing 16S rRNA, showed that the Atlantic salmon gut is colonized by a diverse microbiota, many not previously isolated from the gastrointestinal tract of fish. Bacteria previously isolated include: *Acinetobacter* spp., *Pseudoalteromonas* spp., *Pseudomonas* spp., *Vibrio* spp., *Bacillus* spp., *Carnobacterium piscicola*, *Micrococcus* spp., *Staphylococcus* spp. and *Streptococcus* spp. (Cahill, 1990; Ringø *et al.* 1995; Hansen & Olafsen, 1999; Ringø & Birkbeck, 1999; Ringø & Olsen, 1999).

The following Gram-negative bacteria have not been isolated previously: *Acinetobacter johnsonii*, *Halomonas* spp., *Pseudoalteromonas agarivorans*, *Psychrobacter* spp., *Psychrobacter faecalis*, *Psychrobacter glacincola* and *Psychrobacter submarinus*. Nor have the Gram-positive bacteria *Arthrobacter agilis*, *Jeotgalicoccus psychrophilus*, *Marinilactibacillus psychrotolerans*, *Nocardia corynebacteroides*, *Rathayibacter tritici*, *Rhodococcus* spp., *Staphylococcus equorum* ssp. *linens* and *Staphylococcus pasteurii*. Earlier reviews by Cahill (1990), Ringø *et al.* (1995) and Ringø & Birkbeck (1999) suggested that the gastrointestinal tract microbiota of fish is simpler than that of endothermic animals. However, the present study demonstrates that this statement may need some revision.

The findings of Ringø *et al.* (2006b) and our present findings from Atlantic salmon indicate that *Halomonas* spp. belong to the adherent microbiota in fish and the present observation is therefore a contribution to the knowledge of the microbiota of the fish digestive tract. Recently, information has become available showing the presence of different *Psychrobacter* species in samples from the distal intestine of Arctic charr (Ringø *et al.* 2006b), the alimentary tract of Atlantic salmon (Ringø *et al.* 2006a; the present study), sterile rehydrated salt-cured and dried salt-cured cod (Bjørkevoll *et al.* 2003), the Okhotsk Sea (Yumoto *et al.* 2003) and from deep-sea sediments (Zeng *et al.* 2004).

The Gram-positive, catalase-negative, non-sporulating and motile marine lactic acid bacteria *Marinilactibacillus psychrotolerans* was first isolated and described by Ishikawa *et al.* (2003) from living and decomposing marine organisms collected from the temperate and subtropical areas of Japan. Later *M. psychrotolerans* has been isolated from red-smear soft cheeses (Maoz *et al.* 2003) and deep-sea sediments of the Nankai Trough (Toffin *et al.* 2004) as well as the digestive tract of Atlantic salmon (E Ringø, unpublished results; the present study). This information indicates that this lactic acid bacterium is well adapted to different ecological habitats. The first description of *Staphylococcus pasteurii* was by Chesneau *et al.* (1993), who isolated it from human, animal and food specimens. *S. pasteurii* seems to be well adapted to a wide range of ecological niches as well, since it has been isolated both from stratospheric air samples at 41 km (Wainwright *et al.* 2003) and in the distal intestine of fish fed FM and SBM (the present study).

In conclusion, the involvement of gut microbiota on the pathogenesis of a diet-related mucosal disorder in the teleost Atlantic salmon, SBM-induced enteritis, was not ameliorated by adding the broad-spectrum antibiotic OTC to the diet at 3 g OTC/kg diet. In the distal intestinal mucosa of both SBM and SBM + OTC-fed fish, a significant increase in the PCL as well as apparent increases in the number of cells undergoing cellular repair processes and apoptosis were observed as pathophysiological responses related to the inflammation. However, SBM inclusion in the diet appeared to increase the number and diversity of the microbial community, whereas IN reduced diversity. The implications of the present findings to the intestine's as well as fishes' nutrition and health remain to be elucidated. Further study on the influence of the gastrointestinal microbiota on fish health merit investigation as the global production of fish increases.

Acknowledgements

The authors acknowledge the skilful technical assistance of Birgit Røe for processing of the intestinal tissue, Inger Rudshaug and Laila Aune for excellent work with the immunohistochemistry, and Gjermund Gunnes for expert assistance with the digital image analysis, all at the Norwegian School of Veterinary Science. We are grateful to Suiker Unie for supplying inulin. Financial support for the study was provided by the Research Council of Norway and the Norwegian School of Veterinary Science via the CoE Aquaculture Protein Centre (project number 145949/120).
