An attempt is made to establish the membership of Abell clusters in superclusters of galaxies. The relation

$$
\begin{equation*}
\log z=-3.637+(0.135 \pm 0.014) \mathrm{m}_{10}=(0.179 \pm 0.030) \log \mathrm{P} \tag{1}
\end{equation*}
$$

is used to calibrate the distances to the clusters of galaxies with two redshift estimates. One is m 10 , the magnitude of the ten-ranked galaxy, and the other is the "mean population," P , defined by:

$$
\begin{equation*}
P=p / 2 \pi^{2} \tag{2}
\end{equation*}
$$

where $\mathrm{p}=40,65,105$. . . galaxies for richness groups 0, 1, 2 . . . , and $r$ is the apparent radius in degrees given by:

$$
\begin{equation*}
r=0.0286\left(1+z_{1}\right)^{2} / z_{1} . \tag{3}
\end{equation*}
$$

The first iteration for redshift, $z_{1}$, is obtained from $m_{10}$ alone:

$$
z_{1}=-4.568+0.216 \mathrm{~m}_{10} .
$$

The standard deviation for Eq. (1) is 0.105 , the number of clusters with known velocities is 342 and the correlation coefficient between observed and fitted values is 0.921 . With $z_{i}$ from Eq. (1), we define Cartesian galactic coordinates $X_{i}=R_{i} h^{-1} \cos B_{i} \cos L_{i}, Y_{i}=R_{i} h^{-1} \cos B_{i} \sin L_{i}$, $Z_{i}=R_{i} h^{-1} \operatorname{sinB}_{i}$ for each Abell cluster, $i=1, \ldots, 2712$, where $R_{i}$ is the distance to the cluster ( Mpc ), and $\mathrm{H}_{\mathrm{O}}=100 \mathrm{~h} \mathrm{~km} \mathrm{~s} \mathrm{~s}^{-1} \mathrm{Mpc}^{-1}$.

The mean density of clusters from Abell's sample for $B>50^{\circ}$ is $D_{s}=5.5 \times 10^{-6} \mathrm{~h}^{3} \mathrm{Mpc}^{-3}$ and for all Abell clusters is $\mathrm{D}_{\mathrm{a}}=7.65$ $\times 10^{-6} \mathrm{~h}^{3} \mathrm{Mpc}^{-3}$. These values have been adopted for the entire investigated space and a limiting density $D_{1}$ has been introduced.

Our procedure for supercluster searches consists of the following: Let us take an arbitrary cluster, $C_{1}$, from the catalogue, let $\mathrm{C}_{2}$ be its nearest neighbor, and $\mathrm{O}_{2}$ the mean point between the two clusters. Let the sphere defined by the radius $\mathrm{R}_{2}=\mathrm{O}_{2} \mathrm{C}_{1}=\mathrm{O}_{2} \mathrm{C}_{2}$ have volume $\mathrm{V}_{2}$; the mean density is $\mathrm{D}_{2}$ is $2 / \mathrm{V}_{2}$. If $\mathrm{D}_{2}<\mathrm{D}_{1}$, we conclude the

[^0]examination of cluster $C_{1}$ and pass to another cluster. If $D_{2}>D_{1}$, we look for the third nearest nearest neighbor of $\mathrm{O}_{2}$. Let it be Cluster $C_{3}$. We define $O_{3}$ as a barycenter of the three clusters, supposing equal masses. We determine $\mathrm{V}_{3}$ with radius $\mathrm{R}_{3}=\max \left(\mathrm{O}_{3} \mathrm{C}_{1}, \mathrm{O}_{3} \mathrm{C}_{2}, \mathrm{O}_{3} \mathrm{C}_{3}\right)$ and the mean density is $D_{3}=3 / V_{3}$. If $D_{3}<D_{1}$, we should say that clusters $C_{1}$ and $C_{2}$ form a double cluster. If $D_{3}>D_{1}$, we seek the fourth nearest neighbor of $\mathrm{O}_{3}$, and so on, until we reach $\mathrm{D}_{\mathrm{q}+1}<\mathrm{D}_{\ell}$. In that case, q clusters satisfy the inequality $\mathrm{D}_{\mathrm{q}}>\mathrm{D}_{\ell}$. For a high value of $\mathrm{D}_{\ell}$, we arrive at the same configuration of $q$ clusters, regardless of which cluster is used to start the execution of the described procedure. In this manner, we select triple, quadruple,...clusters.

Among all clusters in Abell's sample, 290 clusters have been identified as participating in multiple clusters ( $q \geq 3$ ), satisfying the condition $D_{l}=50 \mathrm{D}_{\mathrm{S}}$. Some examples: i) A2600 is situated near the center of a supercluster, including A2608, 2606, 2605, 2579, 2580, 2599 and 2583. The diameter is $26 \mathrm{~h}^{-1} \mathrm{Mpc}$ and the mean density is $160 \mathrm{D}_{\mathrm{s}}$; ii) A2540 is near the center of a supercluster with A2531, 2550, 2547, 2521, 2542 and 2509. At a distance of $19 \mathrm{~h}^{-1} \mathrm{Mpc}$ from the center of this supercluster is located A2579 from supercluster i); iii) A1183 is almost in the center of a supercluster with A1201, 1209, 1159 and 1157, with a diameter about $20 \mathrm{~h}^{-1} \mathrm{Mpc}$ and $\overline{\mathrm{D}}=200 \mathrm{D}_{\mathrm{S}}$; iv) A998 is at the center of a supercluster with A1005, 968, 1046 and 1006 , with a diameter $16 \mathrm{~h}^{-1} \mathrm{Mpc}$ and $\bar{D}=400 \mathrm{D}_{\mathrm{S}}$.

Setting $D_{\ell}=10 \mathrm{D}_{\mathrm{S}}$, the number of clusters and members of configurations of high multiplicity increase sharply. The largest configuration then includes 36 clusters and it is around A2550, enclosing i) and ii).

It is interesting to note that the nearest neighbor of some clusters is at a great distance. The mean distance between clusters for the density $D_{s}$ is $31 \mathrm{~h}^{-1} \mathrm{Mpc}$. From the distribution function for the nearest neighbor, we have $\mathrm{F}_{1}(70)=0.9996$, which means that for all clusters in Abell's sample we would expect only one case with a distance greater than $70 \mathrm{~h}^{-1} \mathrm{Mpc}$. Our processing shows that spheres with radii greater than $70 \mathrm{~h}^{-1} \mathrm{Mpc}$ can be drawn around 21 clusters from Abell's sample. Examples are A380, 565, 583, 732, 1451, 1577, 1780, and 2155. Another result concerning all clusters from Abell's catalogue is that almost one-half of the clusters are contained in regions with $\overline{\mathrm{D}}>10 \mathrm{D}$.
