In terms of cost and power conversion efficiency solar cells are considered to be the most promising renewable energy source for the foreseeable future. Additionally, they are pollution free. However, on theoretical grounds, there is room for improvement both in the manufacturing cost and the efficiency of the marketed devices. Indeed, solar cell technology must be developed and improved further to obtain optimal efficiency and cost. As far as the materials employed are concerned, silicon solar cells are the preferred market choice and, for the same reason, have captured more than eighty percent of the current photovoltaic market due to their relatively high efficiency in spite of their relatively high manufacturing cost [1]. On the other hand, the relatively poor UV absorption of crystalline silicon (c-Si) limits the power conversion efficiency that can be attained precluding their proliferation in a larger number of settings. Higher efficiency is, therefore, the greatest challenge for their expanded utilization.

In order to address the aforementioned shortcomings of currently employed silicon solar cells, we describe the synthesis, characterization and incorporation on photovoltaic structures of photoluminescent Cadmium Telluride (CdTe) quantum dots (QDs) that exhibited a size-dependent Stokes shift that could enable dramatic improvements in the power conversion efficiency [2]. To this end, CdTe quantum dots were synthesized, cleaned, collected by centrifugation to promote their precipitation, and dispersed in Poly methyl methacrylate (PMMA) as a matrix for the CdTe quantum dots and deployed on soda lime substrates to study their optical properties.

The excitation wavelengths for the CdTe QDs ranged from 280 to 450 nm and the observed peak emissions ranged from 545 to 623 nm, contingent on the synthesis time. Ostensibly, CdTe QDs enable the down conversion of high energy photons to photons more suitable for electron-hole pair production in Si-based solar cells [3].

The colloidal CdTe quantum dots were synthesized in a water-based solution with the ultimate size being determined by the synthesis time employed. Since the size determines the emission wavelength, evidently it can be tuned by adjusting the chemical reaction time [4]. The characterization effort comprised SEM inspection, photoluminescence (PL), absorption and transmittance. QD size, band gap energy and quantum confinement were calculated employing Brus', Tauc's and Bohr's radius equations. The observations indicate that the judicious utilization of the down shifting effect exhibited by Cadmium Telluride quantum dots have the potential to improve the power conversion efficiency of photovoltaic devices.
